1 Preamble

Guidelines summarize and evaluate available evidence with the aim of assisting health professionals in proposing the best management strategies for an individual patient with a given condition. Guidelines and their recommendations should facilitate decision making of health professionals in their daily practice. However, the final decisions concerning an individual patient must be made by the responsible health professional(s) in consultation with the patient and caregiver as appropriate.

A great number of guidelines have been issued in recent years by the European Society of Cardiology (ESC), as well as by other societies and organizations. Because of their impact on clinical practice, quality criteria for the development of guidelines have been established in order to make all decisions transparent to the user. The recommendations for formulating and issuing ESC Guidelines can be found on the ESC website (https://www.escardio.org/Guidelines/Clinical-Practice-Guidelines/Guidelines-development/Writing-ESC-Guidelines). The ESC Guidelines represent the official position of the ESC on a given topic and are regularly updated.

In addition to the publication of Clinical Practice Guidelines, the ESC carries out the EurObservational Research Programme of international registries of cardiovascular diseases and interventions which are essential to assess, diagnostic/therapeutic processes, use of resources and adherence to Guidelines. These registries aim at providing a better understanding of medical practice in Europe and around the world, based on high-quality data collected during routine clinical practice.

Furthermore, the ESC has developed and embedded in this document a set of quality indicators (QIs), which are tools to evaluate the level of implementation of the Guidelines and may be used by the ESC, hospitals, healthcare providers and professionals to measure clinical practice as well as used in educational programmes, alongside the key messages from the guidelines, to improve quality of care and clinical outcomes.

The Members of this Task Force were selected by the ESC, including representation from its relevant ESC sub-specialty groups, in order to represent professionals involved with the medical care of patients with this pathology. Selected experts in the field undertook a

comprehensive review of the published evidence for management of a given condition according to ESC Committee for Practice Guidelines (CPG) policy. A critical evaluation of diagnostic and therapeutic procedures was performed, including assessment of the risk–benefit ratio. The level of evidence and the strength of the recommendation of particular management options were weighed and graded according to predefined scales, as outlined below.

### 2 Introduction

#### 2.1 Definitions

The clinical presentation of acute coronary syndromes (ACS) is broad. It ranges from cardiac arrest, electrical or haemodynamic instability with cardiogenic shock (CS) due to ongoing ischaemia or mechanical complications such as severe mitral regurgitation, to patients who are already pain free again at the time of presentation. The leading symptom initiating the diagnostic and therapeutic cascade in patients with suspected ACS is acute chest discomfort described as pain, pressure, tightness, and burning. Chest pain-equivalent symptoms may include dyspnoea, epigastric pain, and pain in the left arm. Based on the electrocardiogram (ECG), two groups of patients should be differentiated:

- **Patients with acute chest pain and persistent (>20 min) ST-segment elevation.** This condition is termed ST-segment elevation ACS and generally reflects an acute total or subtotal coronary occlusion. Most patients will ultimately develop ST-segment elevation myocardial infarction (STEMI). The mainstay of treatment in these patients is immediate reperfusion by primary percutaneous coronary intervention (PCI) or, if not available in a timely manner, by fibrinolytic therapy.

- **Patients with acute chest discomfort but no persistent ST-segment elevation [non-ST-segment elevation ACS (NSTE-ACS)] exhibit ECG changes that may include transient ST-segment elevation, persistent or transient ST-segment depression, T-wave inversion, flat T waves, or pseudo-normalization of T waves; or the ECG may be normal.**

The pathological correlate at the myocardial level is cardiomyocyte necrosis [non-ST-segment elevation myocardial infarction (NSTEMI)] or, less frequently, myocardial ischaemia without cell damage (unstable angina). A small proportion of patients may present with ongoing myocardial ischaemia, characterized by one or more of the following: recurrent or ongoing chest pain, marked ST-segment depression on 12-lead ECG, heart failure, and haemodynamic or electrical instability. Due to the amount of myocardium in jeopardy and the risk of developing CS and/or malignant ventricular arrhythmias, immediate coronary angiography and, if appropriate, revascularization are indicated (see section 6).

#### 2.1.1 Universal definition of myocardial infarction

Acute myocardial infarction (AMI) defines cardiomyocyte necrosis in a clinical setting consistent with acute myocardial ischaemia. A combination of criteria is required to meet the diagnosis of AMI, namely the detection of an increase and/or decrease of a cardiac biomarker, preferably high-sensitivity cardiac troponin (hs-cTn) T or I, with at least one value above the 99th percentile of the upper reference limit and at least one of the following:

1. Symptoms of myocardial ischaemia.
2. New ischaemic ECG changes.
3. Development of pathological Q waves on ECG.
4. Imaging evidence of loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology.
5. Intracoronary thrombus detected on angiography or autopsy.

#### 2.1.1.1 Type 1 myocardial infarction

Type 1 myocardial infarction (MI) is characterized by atherosclerotic plaque rupture, ulceration, fissure, or erosion with resulting
in intraluminal thrombus in one or more coronary arteries leading to decreased myocardial blood flow and/or distal embolization and subsequent myocardial necrosis. The patient may have underlying severe coronary artery disease (CAD) but, on occasion (5–10% of cases), there may be non-obstructive coronary atherosclerosis or no angiographic evidence of CAD, particularly in women.1–5

2.1.1.2 Type 2 myocardial infarction
Type 2 MI is myocardial necrosis in which a condition other than coronary plaque instability causes an imbalance between myocardial oxygen supply and demand.3 Mechanisms include hypotension, hypertension, tachyarrhythmias, bradyarrhythmias, anaemia, hypoxaemia, but also by definition, coronary artery spasm, spontaneous coronary artery dissection (SCAD), coronary embolism, and coronary microvascular dysfunction.6–8

2.1.1.3 Types 3–5 myocardial infarction
The universal definition of MI also includes type 3 MI (MI resulting in death when biomarkers are not available) and types 4 and 5 MI (related to PCI and coronary artery bypass grafting (CABG), respectively).3

2.1.2 Unstable angina in the era of high-sensitivity cardiac troponin assays
Unstable angina is defined as myocardial ischaemia at rest or on minimal exertion in the absence of acute cardiomyocyte injury/necrosis. Among unselected patients presenting to the emergency department with suspected NSTE-ACS, the introduction of hs-cTn measurements in place of standard troponin assays resulted in an increase in the detection of MI (~4% absolute and 20% relative increases) and a reciprocal decrease in the diagnosis of unstable angina.9–13

Compared with NSTEMI patients, individuals with unstable angina do not experience acute cardiomyocyte injury/necrosis, have a substantially lower risk of death, and appear to derive less benefit from intensified antplatelet therapy, as well as an invasive strategy within 72 h.13–5.9–19 Pathophysiology and epidemiology are discussed in detail elsewhere.1

2.2 Epidemiology
The proportion of patients with NSTEMI in MI surveys increased from one third in 1995 to more than half in 2015, mainly accounted for by a refinement in the operational diagnosis of NSTEMI20. As opposed to STEMI, no significant changes are observed in the baseline characteristics of the NSTEMI population with respect to age and smoking, while diabetes, hypertension, and obesity increased substantially. The use of early angiography (<72 h from admission) increased from 9% in 1995 to 60% in 2015 (adjusted odds ratio (OR) 16.4, 95% confidence interval (CI) 12.0–22.4, P<0.001) and PCI during the initial hospital stay increased from 12.5% to 67%. The main consequences of these changes are a reduction in 6-month mortality from 17.2% to 6.3% and the adjusted hazard ratio (HR) decreased to 0.40 (95% CI 0.30–0.54) in 2010, remaining stable at 0.40 (0.30–0.52) in 2015.20

2.3 What is new?

New key recommendations

Diagnosis

As an alternative to the ESC 0 h/1 h algorithm, it is recommended to use the ESC 0 h/2 h algorithm with blood sampling at 0 h and 2 h, if an hs-cTn test with a validated 0 h/2 h algorithm is available.

For diagnostic purposes, it is not recommended to routinely measure additional biomarkers such as CK, CK-MB, h-FABP, or copeptin, in addition to hs-cTns.

Risk stratification

Measuring BNP or NT-proBNP plasma concentrations should be considered to gain prognostic information.

Antithrombotic treatment

Prasugrel should be considered in preference to ticagrelor for NSTE-ACS patients who proceed to PCI.

It is not recommended to administer routine pre-treatment with a P2Y12 receptor inhibitor to patients in whom the coronary anatomy is not known and early invasive management is planned.

In patients with NSTE-ACS who cannot undergo an early invasive strategy, pre-treatment with a P2Y12 receptor inhibitor may be considered depending on bleeding risk.

De-escalation of P2Y12 inhibitor treatment (e.g. with a switch from prasugrel or ticagrelor to clopidogrel) may be considered as an alternative DAPT strategy, especially for ACS patients deemed unsuitable for potent platelet inhibition. De-escalation may be done unguided based on clinical judgment, or guided by platelet function testing, or CYP2C19 genotyping depending on the patient’s risk profile and availability of respective assays.

In patients with NSTE-ACS who cannot undergo an early invasive strategy, pre-treatment with a P2Y12 receptor inhibitor may be considered depending on bleeding risk.

Discontinuation of antplatelet treatment in patients treated with OACs is recommended after 12 months.

In patients with NSTE-ACS who cannot undergo an early invasive strategy, pre-treatment with a P2Y12 receptor inhibitor may be considered depending on bleeding risk.

Invasive treatment

An early invasive strategy within 24 h is recommended in patients with any of the following high-risk criteria:
- Diagnosis of NSTEMI
- Dynamic or presumably new contiguous ST/T-segment changes suggesting ongoing ischaemia.
- Transient ST-segment elevation.
- GRACE risk score >140.

A selective invasive strategy after appropriate ischaemia testing or detection of obstructive CAD by CCTA is recommended in patients considered at low risk.

Delayed, as opposed to immediate, angiography should be considered in haemodynamically stable patients without ST-segment elevation successfully resuscitated after an out-of-hospital cardiac arrest.

Complete revascularization should be considered in NSTE-ACS patients without cardiogenic shock and with multivessel CAD.

Complete revascularization during index PCI may be considered in NSTE-ACS patients with multivessel disease.

FFR-guided revascularization of non-culprit NSTE-ACS lesions may be used during index PCI.

Continued
ACS = acute coronary syndromes; AF = atrial fibrillation; BNP = B-type natriuretic peptide; CAD = coronary artery disease; CCTA = coronary computed tomography angiography; CHA2DS2-VASc = Congestive heart failure, Hypertension, Age ≥75 years (2 points), Diabetes, Stroke (2 points) – Vascular disease, Age 65–74, Sex category (female); CK = creatine kinase; CK-MB = creatine kinase myocardial band; DAPT = dual antiplatelet therapy; DAT = dual antithrombotic therapy; ECG = electrocardiogram/electrocardiography; ESC = European Society of Cardiology; FFR = fractional flow reserve; GP = glycoprotein; GRACE = Global Registry of Acute Coronary Events; h-FABP = heart-type fatty acid-binding protein; hs-cTn = high-sensitivity cardiac troponin; MDCT = multidetector computed tomography; MINOCA = myocardial infarction with non-obstructive coronary arteries; NOAC = non-vitamin K antagonist oral anticoagulant; NSTEMI = non-ST-segment elevation acute coronary syndrome; NSTE-ACS = non-ST-segment elevation myocardial infarction; NT-proBNP = N-terminal pro-B-type natriuretic peptide; OAC = oral anticoagulation/anticoagulant; PCI = percutaneous coronary intervention; QI = quality indicator; RCT = randomized controlled trial; SCAD = spontaneous coronary artery dissection; TAT = triple antithrombotic therapy; UFH = unfractionated heparin.

2.4 Number and breakdown of classes of recommendations (Supplementary Data)

The total number of recommendations is 131. The breakdown of the recommendations according to ESC classes of recommendations and levels of evidence are summarized in Supplementary Figure 1.

3 Diagnosis

3.1 Clinical presentation (Supplementary Data)

3.2 Physical examination (Supplementary Data)

3.3 Diagnostic tools

3.3.1 Electrocardiogram

The resting 12-lead ECG is the first-line diagnostic tool in the assessment of patients with suspected ACS (Figure 1). It is recommended to perform it within 10 min of the patient’s arrival in the emergency room or, ideally, at first contact with the emergency medical services in the pre-hospital setting and to have it immediately interpreted by a qualified physician. While the ECG in the setting of NSTE-ACS may be normal in more than 30% of patients, characteristic abnormalities include ST-segment depression, transient ST-segment elevation, and T-wave changes. If the standard leads are inconclusive and the patient has signs or symptoms suggestive of ongoing myocardial ischaemia, additional leads should be recorded; left circumflex artery occlusion may be detected only in V7–V9 or right ventricular MI only in V3R and V4R. In patients with suggestive signs and symptoms, the finding of persistent ST-segment elevation indicates STEMI, which mandates immediate reperfusion. Comparison with previous tracings is valuable, particularly in patients with pre-existing ECG abnormalities. It is recommended to obtain additional 12-lead ECGs in case of persistent or recurrent symptoms or diagnostic uncertainty. In patients with left bundle branch block (LBBB), specific ECG criteria (Sgarbossa’s criteria) may help in the detection of candidates for immediate coronary angiography. Patients with a high clinical suspicion of ongoing myocardial ischaemia and LBBB should be managed in a way similar to STEMI patients, regardless of whether the LBBB is
previously known.2 In contrast, haemodynamically stable patients presenting with chest pain and LBBB only have a slightly higher risk of having MI compared to patients without LBBB. Therefore, the result of the hs-cTn T/I measurement at presentation should be integrated into the decision regarding immediate coronary angiography.24

In patients with right bundle branch block (RBBB), ST-elevation is indicative of STEMI while ST-segment depression in lead I, aVL, and V5/C6 is indicative of NSTE-ACS.25 In patients with paced ventricular beats, the ECG is often of no help for the diagnosis of NSTE-ACS. Novel ECG algorithms using digital ECG data are in development.26–28 In general, it is advisable to perform ECG interpretation using remote technologies at the pre-hospital stage.

It is important to highlight that more than 50% of patients presenting with acute chest pain and LBBB to the emergency department or chest pain unit will ultimately be found to have a diagnosis other than MI.24 Similarly, more than 50% of patients presenting with acute chest pain and RBBB to the emergency department will ultimately be found to have a diagnosis other than MI and should, therefore, also await the result of the hs-cTn T/I measurement at presentation.25

### 3.3.2 Biomarkers: high-sensitivity cardiac troponin

Biomarkers complement clinical assessment and 12-lead ECG in the diagnosis, risk stratification, and treatment of patients with suspected NSTE-ACS. Measurement of a biomarker of cardiomyocyte injury, preferably hs-cTn, is mandatory in all patients with suspected NSTE-ACS.1,3,10 Cardiac troponins are more sensitive and specific markers of cardiomyocyte injury than creatine kinase (CK), its myocardial band isoenzyme (CK-MB), and myoglobin.1,3,4,10–12 Cardiac troponins are more sensitive and specific markers of cardiomyocyte injury than creatine kinase (CK), its myocardial band isoenzyme (CK-MB), and myoglobin. If the clinical presentation is compatible with myocardial ischaemia, then a dynamic elevation of cardiac troponin above the 99th percentile of healthy individuals indicates MI. In patients with MI, levels of cardiac

---

**Figure 1** Diagnostic algorithm and triage in acute coronary syndrome. The initial assessment is based on the integration of low likelihood and/or high likelihood features derived from the clinical setting (i.e. symptoms, vital signs), the 12-lead ECG, and the cardiac troponin concentration determined at presentation to the emergency department and serially thereafter. ‘Other cardiac’ includes among others myocarditis, Takotsubo syndrome, or congestive heart failure. ‘Non-cardiac’ refers to thoracic diseases such as pneumonia or pneumothorax. Cardiac troponin and its change during serial sampling should be interpreted as a quantitative marker: the higher the 0 h level or the absolute change during serial sampling, the higher the likelihood for the presence of MI. In patients presenting with cardiac arrest or haemodynamic instability of presumed cardiovascular origin, echocardiography should be performed/interpreted by trained physicians immediately after a 12-lead ECG. If the initial evaluation suggests aortic dissection or pulmonary embolism, D-dimers and CCTA angiography are recommended according to dedicated algorithms.19–21 CPR = cardiopulmonary resuscitation; ECG = electrocardiogram/electrocardiography; MI = myocardial infarction; NSTEMI = non-ST-segment elevation myocardial infarction; STEMI = ST-segment elevation myocardial infarction. Listen to the audio guide of this figure online.
troponin rise rapidly (i.e. usually within 1 h from symptom onset if using high-sensitivity assays) after symptom onset and remain elevated for a variable period of time (usually several days).1,3,4,10 Advances in technology have led to a refinement in cardiac troponin assays and have improved the ability to detect and quantify cardiomyocyte injury.1,3,4,6,8,10,13,29,30,34,36 Data from large multicentre studies have consistently shown that hs-cTn assays increase diagnostic accuracy for MI at the time of presentation as compared with conventional assays (Figure 2), especially in patients presenting early after chest pain onset, and allow for a more rapid ‘rule-in’ and ‘rule-out’ of MI (see section 3.3.3 and Table 3).1,3,4,6—8,10—13,29,30,35,36 Overall, hs-cTn T and hs-cTn I assays seem to provide comparable diagnostic accuracy in the early diagnosis of MI.37–40

### 3.3.2.1 Central laboratory vs. point-of-care

The vast majority of cardiac troponin assays that are run on automated platforms in the central laboratory are sensitive (i.e. allow for detection of cardiac troponin in ~20–50% of healthy individuals) or high-sensitivity (detection in ~50–95% of healthy individuals) assays. High-sensitivity assays are recommended over less sensitive ones, as they provide higher diagnostic accuracy at identical low cost.1,3,4,6—8,10—13,29,30,35,36

The majority of currently used point-of-care tests (POCTs) cannot be considered sensitive or high-sensitivity assays11. Therefore, the obvious advantage of POCTs, namely the shorter turn-around time, is counterbalanced by lower sensitivity, lower diagnostic accuracy, and lower negative predictive value (NPV). Overall, automated assays have been more thoroughly evaluated than POCTs and seem to be preferable at this point in time.1,3,4,6,8,10,13,29,30,35,36

As these techniques continue to improve, and performance characteristics are both assay and hospital dependent, it is important to re-evaluate this preference once extensively validated high-sensitivity POCTs become clinically available.42 The first hs-cTn I POCTs have recently been shown to provide comparable performance characteristics to that of central laboratory hs-cTn I/T assays.43,44

Many cardiac pathologies other than MI also result in cardiomyocyte injury and, therefore, cardiac troponin elevations (Table 4). Tachyarrhythmias, heart failure, hypertensive emergencies, critical illness, myocarditis, Takotsubo syndrome, and valvular heart disease are the most frequent ones. Most often in elderly patients with renal dysfunction, elevations in cardiac troponin should not be primarily attributed to impaired clearance and considered harmless, as cardiac conditions such as chronic coronary syndromes (CCS) or hypertensive heart disease seem to be the most important contributor to cardiac troponin elevation in this setting.35,45 Other life-threatening conditions presenting with chest pain, such as aortic dissection and pulmonary embolism, may also result in elevated cardiac troponin concentrations and should be considered as differential diagnoses (Table 4).
Table 3  Clinical implications of high-sensitivity cardiac troponin assays

<table>
<thead>
<tr>
<th>Compared with standard cardiac troponin assays, hs-cTn assays:</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Have higher NPV for AMI.</td>
</tr>
<tr>
<td>• Reduce the ‘troponin-blind’ interval leading to earlier detection of AMI.</td>
</tr>
<tr>
<td>• Result in ~4% absolute and ~20% relative increases in the detection of type 1 MI and a corresponding decrease in the diagnosis of unstable angina.</td>
</tr>
<tr>
<td>• Are associated with a 2-fold increase in the detection of type 2 MI.</td>
</tr>
</tbody>
</table>

Levels of hs-cTn should be interpreted as quantitative markers of cardiomyocyte damage (i.e. the higher the level, the greater the likelihood of MI):

| • Elevations beyond 5-fold the upper reference limit have high (>90%) PPV for acute type 1 MI. |
| • Elevations up to 3-fold the upper reference limit have only limited (50–60%) PPV for AMI and may be associated with a broad spectrum of conditions. |
| • It is common to detect circulating levels of cardiac troponin in healthy individuals. |

Rising and/or falling cardiac troponin levels differentiate acute (as in MI) from chronic cardiomyocyte damage (the more pronounced the change, the higher the likelihood of AMI).

AMI = acute myocardial infarction; hs-cTn = high-sensitivity cardiac troponin; MI = myocardial infarction; NPV = negative predictive value; PPV = positive predictive value.

3.3.3.2 Other biomarkers

Among the multitude of additional biomarkers evaluated for the diagnosis of NSTE-ACS, only CK-MB, myosin-binding protein C,46 and copeptin47–58 may have clinical relevance in specific clinical settings when used in combination with cardiac troponin T/I. Compared with cardiac troponin, CK-MB shows a more rapid decline after MI and may provide added value for the timing of myocardial injury and the detection of early reinfarction.1 However, it is important to highlight that little is known on how to best diagnose early reinfarction. Detailed clinical assessment including chest pain characteristics (same characteristics as index event), 12-lead ECG for the detection of new ST-segment changes or T-wave inversion, as well as serial measurement of cardiac troponin T/I and CK/KCK-MB is recommended. Myosin-binding protein C is more abundant than cardiac troponin and may therefore provide value as an alternative to, or in combination with, cardiac troponin.46 Assessment of copeptin, the C-terminal part of the vasopressin prohormone, may quantify the endogenous stress level in multiple medical conditions including MI. As the level of endogenous stress appears to be high at the onset of MI in most patients, the added value of copeptin to conventional (less sensitive) cardiac troponin assays is substantial.49,50,53 Therefore, the routine use of copeptin as an additional biomarker for the early rule-out of MI is recommended in the increasingly uncommon setting where hs-cTn assays are not available. However, copeptin does not have relevant added value for institutions using one of the well-validated hs-cTn-based rapid protocols in the early diagnosis of MI.37,48,51,52,54 Other widely available laboratory variables, such as estimated glomerular filtration rate (eGFR), glucose, and B-type natriuretic peptide (BNP) provide incremental prognostic information and may therefore help in risk stratification.59 The determination of D-dimer is recommended in outpatients/emergency department patients with low or intermediate clinical probability, or those that are unlikely to have pulmonary embolism, to reduce the need for unnecessary imaging and irradiation. D-dimers are key diagnostic elements whenever pulmonary embolism is suspected.32,60

3.3.3 Rapid ‘rule-in’ and ‘rule-out’ algorithms

Due to the higher sensitivity and diagnostic accuracy for the detection of MI at presentation, the time interval to the second cardiac troponin assessment can be shortened with the use of hs-cTn assays. This seems to substantially reduce the delay to diagnosis, translating into shorter stays in the emergency department and lower costs.1,15,16,61–64 It is recommended to use the 0 h/1 h algorithm (best option, blood draw at 0 h and 1 h) or the 0 h/2 h algorithm (second-best option, blood draw at 0 h and 2 h) (Figure 3). These have been
derived and well-validated in large multicentre diagnostic studies using central adjudication of the final diagnosis for all currently available hs-cTn assays. Optimal thresholds for rule-out were selected to allow for a minimal sensitivity and NPV of 99%. Optimal thresholds for rule-in were selected to allow for a minimal positive predictive value (PPV) of 70%. The algorithms were developed in large derivation cohorts and then validated in large independent validation cohorts. As an alternative, the previous European Society of Cardiology (ESC) 0 h/3 h algorithm should be considered. However, three recent large diagnostic studies have suggested that the ESC 0 h/3 h algorithm seems to balance efficacy and safety less well in comparison to more rapid protocols using lower rule-out concentrations including the ESC 0 h/1 h algorithm. Moreover, the very high safety and high efficacy of applying the ESC 0 h/1 h algorithm has recently been confirmed in three real-life implementation studies, including one randomized controlled trial (RCT).

The 0 h/1 h and 0 h/2 h algorithms rely on two concepts: first, hs-cTn is a continuous variable and the probability of MI increases with increasing hs-cTn values, second, early absolute changes of the levels within 1 h or 2 h can be used as surrogates for absolute changes over 3 h or 6 h and provide incremental diagnostic value to the cardiac troponin assessment at presentation. The cut-off concentrations within the 0 h/1 h and 0 h/2 h algorithms are assay specific (Table 5). The NPV for MI in patients assigned ‘rule-out’ exceeded 99% in several large validation cohorts. Used in conjunction with clinical and ECG findings, the 0 h/1 h and 0 h/2 h algorithm will allow the identification of appropriate candidates for early discharge and outpatient management. Even after the rule-out of MI, elective non-invasive or invasive imaging may be indicated according to clinical assessment. Invasive coronary angiography (ICA) will still be the best option in patients with very high clinical likelihood of unstable angina, even after NSTEMI has been ruled out. In contrast, stress testing with imaging or coronary computed tomography angiography (CCTA) will be the best option in patients with low-to-modest clinical likelihood of unstable angina. No testing is necessary in patients with a clear alternative diagnosis.

The PPV for MI in patients meeting the ‘rule-in’ criteria is about 70–75%. Most of the ‘rule-in’ patients with diagnoses other than MI did have conditions that usually still require ICA or cardiac magnetic resonance (CMR) imaging for accurate diagnosis, including Takotsubo syndrome and myocarditis. Therefore, the vast majority of patients triaged towards the rule-in group are candidates for early ICA and admission to a coronary care unit (CCU).

![Figure 3](https://academic.oup.com/eurheartj/advance-article-doi/10.1093/eurheartj/ehaa575/5898842)
These algorithms should always be integrated with a detailed clinical assessment and 12-lead ECG, and repeat blood sampling is mandatory in case of ongoing or recurrent chest pain.

The same concept applies to the 0 h/2 h algorithm. Cut-off levels are assay-specific and shown in Table 5. Cut-off levels for other hs-cTn assays are in development.

### 3.3.4 Observe

Patients who do not qualify for ‘rule-out’ or ‘rule-in’, are assigned to observe. They represent a heterogeneous group that usually requires clinical judgment, non-invasive imaging using CCTA or stress testing [stress echocardiography, positron emission tomography (SPECT), or CMR for the detection of ACS features (oedema, late gadolinium enhancement, perfusion defect, etc.)] should be considered after discharge from the emergency department to the ward. No further diagnostic testing is indicated in patients presenting very early (e.g. <2 h). However, due to the time dependency of troponin release and the only moderate number of patients presenting <1 h after chest pain onset in previous studies, obtaining additional cardiac troponin concentration at 3 h in patients presenting <1 h and triaged towards rule-out should be considered.

As late increases in cardiac troponin have been described in up to 1% of otherwise healthy patients, serial cardiac troponin testing should be pursued if the clinical suspicion remains high or whenever the patient develops recurrent chest pain.

#### 3.3.4.2 Confounders of cardiac troponin concentration

In patients presenting with suspected NSTE-ACS, beyond the presence or absence of MI, four clinical variables affect hs-cTn concentrations:

- Age (to a large extent as a surrogate for pre-existing cardiac disease).
- Renal dysfunction (to a large extent as a surrogate for pre-existing cardiac disease).
- Event time from chest pain onset.
- Sex.

### 3.3.4.1 Caveats of using rapid algorithms

When using any algorithm, three main caveats apply:

- Algorithms should only be used in conjunction with all available clinical information, including detailed assessment of chest pain characteristics and ECG.
- The ESC 0 h/1h and 0 h/2 h algorithms apply to all patients irrespective of chest pain onset. The safety (as quantified by the NPV) and sensitivity are very high (>99%), including in the subgroup of patients presenting very early (<2 h). However, due to the time dependency of troponin release and the only moderate number of patients presenting <1 h after chest pain onset in previous studies, obtaining an additional cardiac troponin concentration at 3 h in patients presenting <1 h and triaged towards rule-out should be considered.

#### 3.3.4.1 Caveats of using rapid algorithms

When using any algorithm, three main caveats apply:

- i. Algorithms should only be used in conjunction with all available clinical information, including detailed assessment of chest pain characteristics and ECG.

These cut-offs apply irrespective of age and renal function. Optimized cut-offs for patients above 75 years of age and patients with renal dysfunction have been evaluated, but not consistently shown to provide better balance between safety and efficacy as compared to these universal cut-offs. The algorithms for additional assays are in development.
the use of uniform cut-off concentrations should remain the standard of care in the early diagnosis of MI.35,36,39,68,69,75,76

3.3.4.3 Practical guidance on how to implement the European Society of Cardiology 0 h/1 h algorithm
In order to maximize the safety and feasibility of the process, the nursing team should, in general, obtain blood samples for hs-cTn at 0 h and 1 h irrespective of other clinical details and pending results. This introduces unnecessary cardiac troponin measurements in perhaps 10–15% of patients with very low 0 h concentrations and chest pain onset >3 h, but substantially facilitates the process and thereby further increases patient safety. Documentation of the time of the 0 h blood draw allows exact determination of the time window (± 10 min) of the 1 h blood draw. If the 1 h (± 10 min) blood draw was not feasible, then blood should be drawn at 2 h and the ESC 0 h/2 h algorithm applied.

3.3.4.4 Avoiding misunderstandings: time to decision = time of blood draw + turn-around time
The use of the ESC 0 h/1 h algorithm is irrespective of the local turn-around time. 0 h and 1 h refer to the time point at which blood is taken (Figure 4).

---

**Figure 4** Timing of the blood draws and clinical decisions when using the European Society of Cardiology 0 h/1 h algorithm. 0 h and 1 h refer to the time points at which blood is taken. The turn-around time is the time period from blood draw to reporting back the results to the clinician. It is usually about 1 h using an automated platform in the central laboratory. It includes transport of the blood tube to the lab, scanning of the probe, centrifugation, putting plasma on the automated platform, the analysis itself, and the reporting of the test result to the hospital information technology/electronic patient record. The turn-around time is identical whether using a hs-cTn assay vs. a conventional assay, as long as both are run on an automated platform. Adding the local turn-around time to the time of blood draw determines the earliest time point for clinical decision making based on hs-cTn concentrations. e.g. for the 0 h time point, time to decision is at 1 h if the local turn-around time is 1 h. For the blood drawn at 1 h, the results are reported back at 2 h (1 h + 1 h) if the local turn-around time is 1 h. Relevant 1 h changes are assay dependent and listed in Table 3. CPO = chest pain onset; CPR = cardiopulmonary resuscitation; ECG = electrocardiogram/electrocardiography; hs-cTn = high-sensitivity cardiac troponin; MACE = major adverse cardiovascular events; MI = myocardial infarction. Listen to the audio guide of this figure online.
The clinical and economic benefit of the ESC 0 h/1 h algorithm vs. the ESC 0 h/3 h algorithm or other algorithms with the second blood draw later than 1 h is therefore independent of the local turn-around time.61

3.3.5 Non-invasive imaging

3.3.5.1 Functional evaluation

Transthoracic echocardiography should be routinely available in emergency rooms and chest pain units and performed/interpreted by trained physicians in all patients during hospitalization for NSTE-ACS. This imaging modality is useful to identify abnormalities suggestive of myocardial ischaemia or necrosis (i.e. segmental hypokinesia or akinesia). In the absence of significant wall motion abnormalities, impaired myocardial perfusion detected by contrast echocardiography or reduced regional function using strain and strain rate imaging might improve the diagnostic and prognostic value of conventional echocardiography.94–96 Moreover, echocardiography can help in detecting alternative pathologies associated with chest pain, such as acute aortic dissection, pericardial effusion, aortic valve stenosis, hypotrophic cardiomyopathy, mitral valve prolapse, or right ventricular dilatation suggestive of acute pulmonary embolism. Similarly, echocardiography is the diagnostic tool of choice for patients with haemodynamic instability of suspected cardiac origin.96,97 Evaluation of left ventricular (LV) systolic function, at the latest by the time of hospital discharge, is important to estimate prognosis, and echocardiography (as well as other imaging modalities) can provide this information.

In patients without ischaemic changes on 12-lead ECGs and normal hs-cTn, who are free from chest pain for several hours, stress imaging can be performed during hospitalization or shortly after discharge. Stress imaging is preferred over exercise ECG due to its greater diagnostic accuracy.98 Various studies have shown that normal exercise or dipyridamole stress echocardiograms have high NPV for ischaemia and are associated with excellent patient outcomes.99,100 Moreover, stress echocardiography has demonstrated superior prognostic value over exercise ECG.101 If the acoustic window is not adequate to assess regional wall motion abnormalities, the use of echocardiographic contrast is recommended to improve the accuracy of such an assessment and facilitate the detection of ischaemia.98,101–103

CMR can assess both perfusion and wall motion abnormalities, and patients presenting with acute chest pain with a normal stress CMR have an excellent short- and mid-term prognosis.104 Additionally, CMR permits detection of scar tissue (using late gadolinium enhancement) and can differentiate this from recent infarction (using T2-weighted imaging to delineate myocardial oedema).105 Moreover, CMR can facilitate the differential diagnosis between infarction, myocarditis, or Takotsubo syndrome, among others.98 In a recent randomized trial in patients with unclear NSTE-ACS diagnosis, upfront imaging with CMR reduced the need for ICA and provided an alternative diagnosis in a relevant proportion of patients.105

Similarly, SPECT has been shown to be useful for the risk stratification of patients with acute chest pain suggestive of ACS. Resting myocardial scintigraphy, by detecting fixed perfusion defects suggestive of myocardial necrosis, can be helpful for the initial triage of patients presenting with chest pain without ECG changes or elevated cardiac troponins.99 Combined stress — rest imaging and/or stress-only imaging may further enhance assessment of ischaemia, while a normal study is associated with an excellent outcome.106,107 Stress — rest imaging modalities are usually not widely available on 24 h service and some (e.g. SPECT) are associated with substantial radiation exposure.

3.3.5.2 Anatomical evaluation

CCTA allows visualization of the coronary arteries and a normal scan excludes CAD. CCTA has a high NPV to exclude ACS (by excluding CAD) and an excellent outcome in patients presenting to the emergency department with low-to-intermediate pre-test probability for ACS and a normal CCTA.108 Seven RCTs have tested CCTA vs. usual care in the triage of low-to-intermediate-risk patients presenting with acute chest pain to emergency departments without signs of ischaemia on ECG and normal cardiac troponins.109 However, the majority of studies used only conventional, less sensitive assays.110–113 At a follow-up of 1–6 months, there were no deaths, and a meta-analysis demonstrated comparable outcomes with the two approaches (i.e. no difference in the incidence of MI, post-discharge emergency department visits, or re-hospitalizations) and showed that CCTA was associated with a reduction in emergency department costs and length of stay.114 However, none of these studies used hs-cTn assays, which also reduce hospital stay. In a randomized study, in which the standard of care included hs-cTn, CCTA was no longer able to improve patient flow.115 It was also noted that CCTA was associated with an increase in the use of invasive angiography.114 In contrast, in a recent randomized trial of unclear NSTEMI diagnosis, upfront imaging with CCTA reduced the need for ICA.105 Similar results were observed in a sub-analysis of the Very EaRly vs Deferred Invasive evaluation using Computed Tomography (VERDICT) trial, where upfront CCTA in NSTEMI ACS patients had an NPV of 90.9%.116 However, a relatively large patient group had to be excluded for specific reasons and an NPV of 90.9% is not entirely perfect.116 Accordingly, CCTA can be used to exclude CAD and is thus less useful in patients with known CAD. Other factors limiting CCTA include severe calcifications (high calcium score) and elevated or irregular heart rate; in addition, a 24 h service is currently not widely available. Finally, the use of CCTA in the acute setting in patients with stents or previous CABG has not been validated. Importantly, computed tomography (CT) imaging can effectively exclude other causes of acute chest pain that, if untreated, are associated with high mortality, namely pulmonary embolism and aortic dissection.

3.4 Differential diagnosis

Among unselected patients presenting with acute chest pain to the emergency department, disease prevalence can be expected to be the following: 5–10% STEMI, 15–20% NSTEMI, 10% unstable angina, 15% other cardiac conditions, and 50% non-cardiac diseases.35,36,39,69,79,87–93 Several cardiac and non-cardiac conditions may mimic NSTE-ACS (Table 6).

Conditions that should always be considered in the differential diagnosis of NSTE-ACS because they are potentially life-threatening but also treatable include acute dissection, pulmonary embolism, and tension pneumothorax. Echocardiography should be performed urgently in all patients with haemodynamic instability of suspected cardiovascular origin. Takotsubo syndrome has recently been
observed more often as a differential diagnosis and usually requires coronary angiography to rule out ACS.117

Chest X-ray is recommended in all patients in whom NSTE-ACS is considered unlikely in order to detect pneumonia, pneumothorax, rib fractures, or other thoracic disorders. Stroke may be accompanied by ECG changes, myocardial wall motion abnormalities, and cardiomyocyte injury (= increase in cardiac troponin concentrations). The majority of patients presenting to the emergency department with acute chest pain have non-cardiac conditions causing the chest discomfort.35,36,39,69,79,87–93 In many instances, the pain is musculoskeletal and is therefore benign, self-limiting, and does not require hospitalization. Chest pain characteristics help to some extent—in the early identification of these patients.

Continued
4 Risk assessment and outcomes

4.1 Electrocardiogram indicators (Supplementary Data)

4.2 Biomarkers

Beyond diagnostic utility, initial cardiac troponin levels add prognostic information in terms of short- and long-term mortality to clinical and ECG variables. While hs-cTn T and I have comparable diagnostic accuracy, hs-cTn T has greater prognostic accuracy.38,119 Serial measurements are useful to identify peak levels of cardiac troponin for risk stratification purposes in patients with established MI. The higher the hs-cTn T levels, the greater the risk of death.124,125 However, evidence is limited regarding the optimal time points of serial hs-cTn T measurement. Serum creatinine and eGFR should also be determined in all patients with NSTE-ACS because they affect prognosis and are key elements of the Global Registry of Acute Coronary Events (GRACE) risk score (see section 4.3). Similarly, natriuretic peptides [BNP and N-terminal pro-BNP (NT-proBNP)] provide prognostic information regarding the risk of death, acute heart failure, as well as the development of AF in addition to cardiac troponin.121 In addition, quantifying the presence and severity of haemodynamic stress and heart failure using BNP or NT-proBNP concentrations in patients with left main CAD or three-vessel CAD without NSTE-ACS may help the heart team to select either PCI or CABG as the revascularization strategy of choice.122–124 However, this needs confirmation in randomized trials and has not been tested in NSTE-ACS patients so far. Similarly, natriuretic peptides provide prognostic information on top of cardiac troponin.121,125,126 Other biomarkers, such as high-sensitivity C-reactive protein, mid-regional pro-adrenomedullin, growth differentiation factor 15 (GDF-15), heart-type fatty acid-binding protein (h-FABP), and copeptin may also have some prognostic value.50,118,127 However, the assessment of these markers has, so far, not been shown to improve patient management and their added value in risk assessment on top of the GRACE risk calculation and/or BNP/NT-proBNP seems marginal. At the present time, the routine use of these biomarkers for prognostic purposes is not recommended.

4.3 Clinical scores for risk assessment (Supplementary Data)

A number of prognostic models that aim to estimate the future risk of all-cause mortality or the combined risk of all-cause mortality or MI have been developed. These models have been formulated into clinical risk scores and, among these, the GRACE risk score offers the best discriminative performance.133–135 It is important to recognize, however, that there are several GRACE risk scores, and each refers to different patient groups and predicts different outcomes.136–137 The GRACE risk score models have been externally validated using observational data.140 Further information concerning the GRACE risk scores is presented in Supplementary Data section 4.3, Supplementary Table 1,
and Supplementary Figure 3. The nomogram to calculate the original GRACE risk score, which estimates the risk of in-hospital death, is shown in Supplementary Figure 3 and online risk calculators are available for other GRACE risk scores: https://www.outcomes.umassmed.org/risk_models_grace_orig.aspx for the GRACE risk score 1.0 and www.outcomes.umassmed.org/grace/acs_risk2/index.html for the GRACE risk score 2.0.

Given that the GRACE risk score predicts clinical outcomes, it is possible to stratify patients according to their estimated risk of future ischaemic events. A GRACE risk score-based risk assessment has been found to be superior to (subjective) physician assessment for the occurrence of death or MI.\(^{141,142}\) Moreover, it is well recognized that the delivery of guideline-directed care is inversely related to the estimated risk of the patient with NSTE-ACS\(^{193}\) — the so called ‘risk-treatment paradox’.\(^{144,145}\) Guideline-directed care is associated with proportionally greater survival gains among those with higher baseline risk, therefore objective risk assessment may help to identify NSTE-ACS patients who would benefit from risk-determined care interventions.\(^{144,145}\) The Australian GRACE Risk Score Intervention Study (AGRIS)\(^{146}\) and the ongoing UK GRACE Risk Score Intervention Study (UKGRIS)\(^{147}\) have — or are for the first time — investigating the impact of the utilization of the GRACE risk score on outcomes of patients with NSTE-ACS in a randomized manner. The AGRIS cluster-randomized trial failed to demonstrate any add-on value, especially for the guideline-directed treatments with the routine implementation of the GRACE risk score. This was largely explained by better-than-expected performance of the control hospitals. Given temporal improvements in early mortality from NSTE-ACS,\(^{148}\) the prediction of long-term risk is important. Deaths in the early phase following NSTE-ACS are more attributable to ischaemia/thrombosis-related events, whereas in the later phase they are more likely to be associated with the progression of atherosclerosis and non-cardiovascular causes.\(^{149–152}\)

### 4.4 Bleeding risk assessment

Major bleeding events are associated with increased mortality in NSTE-ACS.\(^{157}\) In order to estimate bleeding risk in this setting, scores such as the Can Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/American Heart Association (AHA) guidelines (CRUSADE: https://www.mdcalc.com/crusade-score-post-mi-bleeding-risk) and the Acute Catheterization and Urgent Intervention Triage strategY (ACUITY) bleeding risk scores have been developed. Overall, the two scores have reasonable predictive value for major bleeding in ACS patients undergoing coronary angiography, with CRUSADE being the most discriminatory.\(^{155–157}\) Changes in interventional practice, such as the use of radial access for coronary angiography and PCI, as well as in antithrombotic treatment, may modify the predictive value of risk scores. In addition, in medically treated patients or those on oral anticoagulants (OACs), the predictive value of these scores has not been established. Given these limitations, the use of the CRUSADE bleeding risk score may be considered in patients undergoing coronary angiography to quantify bleeding risk.

An alternative to these scores may be the assessment of bleeding risk according to the Academic Research Consortium for High Bleeding Risk (ARC-HBR) (Table 7).\(^{158}\) This consensus definition of patients at high bleeding risk (HBR) was recently developed to provide consistency for clinical trials evaluating the safety and effectiveness of devices and drug regimens for patients undergoing PCI.\(^{158}\) This proposed ARC-HBR represents a pragmatic approach that includes the most recent trials performed in HBR patients, who were previously excluded from clinical trials of dual antiplatelet therapy (DAPT) duration or intensity (Table 7).\(^{159–161}\) However, bleeding risk assessment based on ARC-HBR criteria may be difficult to apply in routine clinical practice as several of the criteria are quite detailed and so far, this score has not been validated.

\(\text{aClass of recommendation.}\)

\(\text{bLevel of evidence.}\)
Major bleeding events affect prognosis in a similar way to spontaneous ischaemic complications.\textsuperscript{163,164} Given the trade-off between ischaemic vs. bleeding risks for any antithrombotic regimen, the use of scores might prove useful to tailor antithrombotic duration, as well as intensity, to maximize ischaemic protection and minimize bleeding risk in the individual patient. Specific risk scores have been developed for patients on DAPT following PCI, in the setting of both CCS as well as ACS. To date, no risk score has been tested in patients requiring long-term anticoagulation. The DAPT and the PREdicting bleeding Complications In patients undergoing Stent implantation and subEquent Dual Anti Platelet Therapy (PRECISE-DAPT) scores have been designed to guide and inform decision making on DAPT duration.\textsuperscript{153,154} The applicability of the PRECISE-DAPT score is at patient discharge, while the DAPT score is a bleeding risk estimation to be calculated at 1 year from the index event. The usefulness of the PRECISE-DAPT score was retrospectively assessed within patients randomized to different DAPT durations (n = 10 081) to identify the effect on bleeding and ischaemia of a long (12–24 months) or short (3–6 months) treatment duration in relation to baseline bleeding risk.\textsuperscript{154} Among HBR patients based on PRECISE-DAPT (i.e. PRECISE-DAPT score ≥25), prolonged DAPT was associated with no ischaemic benefit but a large bleeding burden.\textsuperscript{154} Conversely, longer treatment in patients without HBR (i.e. PRECISE-DAPT score <25) was associated with no increase in bleeding and a significant reduction in the composite ischaemic endpoint of MI, definite stent thrombosis, stroke, and target vessel revascularization. The findings remained valid in analyses restricted to ACS. However, for the majority of patients in the study, DAPT consisted of aspirin and clopidogrel. An external validation of the PRECISE-DAPT score — in 4424 ACS patients undergoing PCI and treated with prasugrel or ticagrelor — showed a modest predictive value for major bleeding at a median follow-up of 14 months (c-statistic = 0.653).\textsuperscript{165} In addition, none of these risk prediction models have been prospectively tested in RCTs, therefore, their value in improving patient outcomes remains unclear. The DAPT study has been less well validated, with a retrospective analysis in 1970 patients and a score calculation at a different time point (6 vs. 12 months) than in the derivation cohort used to generate the score.\textsuperscript{166}

## 5 Pharmacological treatments

### 5.1 Antithrombotic treatment

Antithrombotic treatment is mandatory in NSTE-ACS patients with and without invasive management. Its choice, the combination, the time point of initiation, and the treatment duration depend on various intrinsic and extrinsic (procedural) factors (Figure 5). Notably, both ischaemic and bleeding complications significantly influence the outcome of NSTE-ACS patients and their overall mortality risk.\textsuperscript{167} Thus, the choice of treatment should equally reflect the ischaemic and bleeding risk of the patient.

Recommended anticoagulant and antiplatelet drugs and their dosing (for use during and after NSTE-ACS) are summarized in Figure 6 and Table 8.

**5.1.1 Antiplatelet drugs and pre-treatment**

**5.1.1.1 Antiplatelet drugs and dual antiplatelet therapy**

Activation of blood platelets and the coagulation cascade play a key role in the initial phase and evolution of NSTE-ACS. Hence, sufficient platelet inhibition and (temporary) anticoagulation is essential in NSTE-ACS patients, especially in those undergoing myocardial revascularization by PCI. Aspirin is considered to be the cornerstone of treatment for inhibition of thromboxane A₂ generation (Figure 6), which is normally complete with a dose ≥75 mg/d. Aspirin treatment is started with a loading dose (LD) followed by maintenance treatment (Table 8). Current evidence supports a maintenance dose (MD) of 75–100 mg once daily (o.d.). Based on the results of the phase III PLATElet inhibition and patient Outcomes (PLATO) and TRial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet InhibiToN with Prasugrel—Thrombolysis In Myocardial Infarction 38 (TRITON-TIMI 38) trials, including aspirin and a potent P₂Y₁₂ receptor inhibitor (ticagrelor or prasugrel) is the recommended standard treatment for NSTE-ACS patients. Clopidogrel, characterized by less potent and variable platelet inhibition, should only be used when prasugrel or ticagrelor are contraindicated, not available, or cannot be tolerated due to an unacceptable HBR. P₂Y₁₂ receptor inhibitors differ with respect to their pharmacokinetic and pharmacodynamic properties. Table 9 summarizes the essential features of the available oral and intravenous (i.v.) drugs. For further details on recent DAPT trials, please refer to the 2017 ESC focused update on DAPT in CAD.

Trial data on the head-to-head comparison of prasugrel vs. ticagrelor became available with the open-label randomized Intracoronary stenting and Antithrombotic regimen—Rapid Early Action for Coronary Treatment (ISAR-REACT) 5 trial. This study was conducted in 4018 ACS patients (NSTE-ACS and STEMI) for whom an invasive evaluation was planned. The trial demonstrated that treatment with prasugrel vs. ticagrelor significantly reduced the composite rate of death, MI, or stroke (6.9 vs. 9.3%, P=0.006) without any increase in bleeding complications (4.8 vs. 5.4%, P=0.46). Limitations...
of the study, amongst multiple others, include its open-label design and the limited data on medically managed or CABG-treated patients, which were more prominent in the PLATO trial. Ticagrelor also led to more patients stopping medication because of side effects. The actual treatment strategy was PCI in >80% of randomized patients and, consequently, prasugrel should be considered the preferred P2Y12 receptor inhibitor for NSTE-ACS patients who proceed to PCI. The possible benefit of prasugrel, in comparison with ticagrelor or clopidogrel, may be related to improved endothelial function. Recommended treatment algorithms and treatment durations, as well as options for extended treatment (>12 months) in NSTE-ACS patients, are shown in Figure 7.

5.1.1.2 Pre-treatment
Pre-treatment defines a strategy according to which antiplatelet drugs, usually a P2Y12 receptor inhibitor, are given before coronary angiography and when the coronary anatomy is unknown. Although a rationale for pre-treatment in NSTE-ACS may seem obvious, for achieving sufficient platelet inhibition at the time of PCI, large-scale randomized trials supporting a routine pre-treatment strategy with either clopidogrel or the potent P2Y12 receptor inhibitors - prasugrel and ticagrelor - are lacking. The randomized Comparison of Prasugrel at the Time of Percutaneous Coronary Intervention or as Pretreatment at the Time of Diagnosis in Patients with Non-ST Elevation Myocardial Infarction (ACCOAST) trial demonstrated a lack of any ischaemic benefit for pre-treatment in NSTE-ACS patients, but instead, a substantially higher bleeding risk with prasugrel pre-treatment. In line with these results, observational data on pre-treatment with ticagrelor, prasugrel, and clopidogrel were reported from the Swedish Coronary Angiography and Angioplasty Registry (SCAAR) in 64 857 NSTE-ACS patients. In this large dataset on pre-treatment, the authors reported that P2Y12 receptor inhibitor pre-treatment in NSTE-ACS patients was not associated with improved ischaemic outcomes, but instead, with a significantly increased risk of bleeding events. With respect to pre-treatment data for ticagrelor, the recently published ISAR-REACT 5 trial showed that a prasugrel-based strategy with deferred loading after knowledge of coronary anatomy in NSTE-ACS patients was superior to a ticagrelor-based strategy that implied a routine pre-treatment strategy. Importantly, there was no apparent benefit of a pre-treatment strategy (that utilized ticagrelor) in that study.

Based upon the available evidence, it is not recommended to administer routine pre-treatment with a P2Y12 receptor inhibitor in NSTE-ACS patients in whom coronary anatomy is not known and an early invasive management is planned. For patients with a delayed invasive management, pre-treatment with a P2Y12 receptor inhibitor may be considered in selected cases and according to the bleeding risk of the patient. Fortunately, the recommended standard treatment with potent P2Y12 receptor inhibitors (ticagrelor or prasugrel) exhibits a fast onset of action (Table 9), thereby allowing LD administration after diagnostic coronary angiography and directly before PCI. Of note, a routine pre-treatment strategy may be deleterious for a relevant proportion of patients with diagnoses other than NSTE-ACS (e.g. aortic dissection or bleeding complications including intracranial bleeding) and may increase bleeding risk or delay procedures in patients scheduled for CABG after diagnostic angiography.

Algorithm for antithrombotic therapy in non-ST-segment elevation acute coronary syndrome patients without atrial fibrillation undergoing percutaneous coronary intervention. HBR is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score >25 or ARC-HBR158). Colour-coding refers to the ESC classes of recommendations (green = class I; yellow = IIa; orange = Class IIb). Very HBR is defined as recent bleeding in the past month and/or not deferrable planned surgery. A = aspirin; ARC-HBR = Academic Research Consortium/High Bleeding Risk; C = clopidogrel; DAPT = dual antiplatelet therapy; DAT = dual antithrombotic therapy (here: aspirin + rivaroxaban); eGFR = estimated glomerular filtration rate; ESC = European Society of Cardiology; HBR = high bleeding risk; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; P = prasugrel; PCI = percutaneous coronary intervention; PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsequent Dual Anti Platelet Therapy; R = rivaroxaban; T = ticagrelor; UFH = unfractionated heparin. aClopidogrel during 12 months DAPT if patient is not eligible for treatment with prasugrel or ticagrelor or in a setting of DAPT de-escalation with a switch to clopidogrel (class IIb). bClopidogrel or prasugrel if patient is not eligible for treatment with ticagrelor. cClass Ila indication for DAT or DAPT >12 months in patients at high risk for ischaemic events (see Table 9 for definitions) and without increased risk of major bleeding (= prior history of intracranial haemorrhage or ischaemic stroke, history of other intracranial pathology, recent gastrointestinal bleeding or anaemia due to possible gastrointestinal blood loss, other gastrointestinal pathology associated with increased bleeding risk, liver failure, bleeding diathesis or coagulopathy, extreme old age or frailty, renal failure requiring dialysis, or with eGFR <15 mL/min/1.73 m²); Class IIb indication for DAT or DAPT >12 months in patients with moderately increased risk of ischaemic events (see Table 9 for definitions) and without increased risk of major bleeding. Listen to the audio guide of this figure online.
The respective drugs should be discontinued immediately after PCI, except in specific clinical settings such as the confirmed presence of LV aneurysm with thrombus formation or AF requiring anticoagulation, which is usually done with UFH in (per)-acute settings. Adjunctive treatment [e.g. glycoprotein (GP) IIb/IIIa inhibitors] and procedural aspects (radial vs. femoral access) have been subject to change in recent years. In contrast to older studies, recent and contemporary trials have pursued a balanced and more selective use of GP IIb/IIIa inhibitors, with both bivalirudin and UFH. These trials have been reviewed extensively in a number of meta-analyses.

5.1.2 Peri-interventional anticoagulant treatment

Peri-interventional treatment for NSTE-ACS patients consists of anticoagulation to inhibit thrombin generation and thrombin activity (Figure 6). Anticoagulation is recommended for all patients in addition to antplatelet therapy during invasive management for NSTE-ACS. Table 8 provides an overview of the relevant drugs and their dosing in NSTE-ACS patients. Unfractionated heparin (UFH) is the standard of care for NSTE-ACS patients due to its favourable risk-benefit profile. In general, a crossover between anticoagulants should be avoided [especially between UFH and low-molecular-weight heparin (LMWH)], with the exception of adding UFH to fondaparinux when a patient proceeds to PCI after fondaparinux treatment.
Implementation of angioX (MATRIX) trial showed no significant benefit of bivalirudin vs. UFH for ischaemic outcomes. Bivalirudin was associated with a significant increase in the risk of stent thrombosis and a significant decrease in bleeding risk. Bleeding risk reduction was linked to unbalanced use of GP IIb/IIIa inhibitors, predominantly with UFH. Recently, the Swedish Web-system for Enhancement and Development of Evidence-based care in Heart disease Evaluated According to Recommended Therapies (VALIDATE-SWEDEHEART) study compared UFH vs. bivalirudin on a background of radial access and limited use of GP IIb/IIIa inhibitors. The study demonstrated similar risks for both ischaemia and bleeding when comparing the two drugs. Another meta-analysis, updated with the results of the VALIDATE-SWEDEHEART study, confirmed that bivalirudin vs. UFH was associated with a similar incidence of all-cause death and ischaemic events after PCI in ACS. A significant association between bivalirudin and decreased risk of bleeding was only found with unbalanced use of GP IIb/IIIa inhibitors in conjunction with UFH.

In summary, and based on the aforementioned trials, UFH is primarily recommended as an anticoagulant for PCI. Due to its short half-life and favourable results in some of the studies, bivalirudin may be considered as an alternative to UFH in selected cases. For a more detailed description and a historical summary of the older clinical trials (with unbalanced use of GP IIb/IIIa inhibitors) comparing UFH with bivalirudin, please refer to the 2018 ESC/EACTS Guidelines on myocardial revascularization.

Patients may undergo cardiac catheterization after a conservative treatment phase and these patients might be treated with fondaparinux during this period. This regimen is based on the Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS-5) trial. Of note, catheter thrombus formation was an issue with fondaparinux and, therefore, full-dose UFH must be added to prevent thrombus formation when the patient proceeds to PCI.

Enoxaparin, a LMWH with a predictable dose-effect relationship and a lower risk for heparin-induced thrombocytopenia (HIT) compared to UFH, should be considered as an anticoagulant for PCI in patients pre-treated with subcutaneous enoxaparin. A benefit of enoxaparin over UFH — reduced mortality and bleeding complications — was reported in a meta-analysis that included NSTE-ACS patients, but dedicated large-scale trials comparing enoxaparin vs. UFH in NSTE-ACS are lacking.

5.1.3 Peri-interventional antiplatelet treatment

Drugs for peri-interventional i.v. antiplatelet treatment include cangrelor and GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban). Most of the trials evaluating GP IIb/IIIa inhibitors in PCI-treated ACS patients predated the era of routine DAPT with early DAPT initiation including a P2Y12 receptor inhibitor LD. Today, with routine and potent oral P2Y12 receptor inhibitors, there is no compelling evidence for an additional benefit of routine upstream use of GP IIb/IIIa inhibitors in NSTE-ACS patients scheduled for coronary angiography. Even more so, in a setting of potent platelet inhibition with ticagrelor or prasugrel, where randomized data on GP IIb/IIIa use is limited, routine use of these agents cannot be recommended. Nevertheless, use should be considered for bail-out situations or thrombotic complications and may be considered for high-risk PCI in patients without pre-treatment with P2Y12 receptor inhibitors (see 2018 ESC/EACTS Guidelines on myocardial revascularization for more details).

Cangrelor is a direct reversible, short-acting P2Y12 receptor inhibitor that has been evaluated during PCI for stable CCS and ACS in clinical trials comparing cangrelor with clopidogrel, administered before PCI (Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION) or after PCI (CHAMPION PLATFORM and CHAMPION PHOENIX). A meta-analysis of these trials showed a benefit with respect to major ischaemic endpoints that was counter-balanced by an increase in minor bleeding complications. Moreover, the benefit of cangrelor with respect to ischaemic endpoints was attenuated in CHAMPION PCI with upfront administration of clopidogrel, while data for its use in conjunction with ticagrelor or prasugrel treatment are limited. Due to its proven efficacy in preventing intra-procedural and post-procedural stent thrombosis in P2Y12 receptor inhibitor-naïve patients, cangrelor may be considered on a case-by-case basis in P2Y12 receptor inhibitor-naïve NSTE-ACS patients undergoing PCI (see 2018 ESC/EACTS Guidelines on myocardial revascularization for more details).

5.1.4 Post-interventional and maintenance treatment

Following PCI for NSTE-ACS, DAPT consisting of a potent P2Y12 receptor inhibitor in addition to aspirin is generally recommended for 12 months, irrespective of the stent type, unless there are contra-indications. In specific clinical scenarios, DAPT duration can be shortened (<12 months), extended (>12 months, see Figure 7 and Tables 10 and 11), or modified (switching DAPT, DAPT de-escalation) and these decisions depend on individual clinical judgement being driven by the patient’s ischaemic and bleeding risk, the occurrence of adverse events, comorbidities, co-medications, and the availability of the respective drugs. For a detailed description of the pertinent and numerous trials that have compared different DAPT treatment durations (especially 3–6 vs. 12 months in NSTE-ACS patients), please refer to the 2017 ESC focused update on DAPT in CAD and recent trial publications. In patients with NSTE-ACS and stent implantation who are at high risk of bleeding (e.g. PRECISE-DAPT ≥25 or ARC-HBR criteria met), discontinuation of P2Y12 receptor inhibitor therapy after 3–6 months should be considered. In patients at very high risk of bleeding, defined as a recent bleeding episode in the past month or planned, not deferred surgery in the near future, 1 month of aspirin and clopidogrel should be considered.

Four recent trials (n = 29 089) have explored the benefit of a shortened DAPT duration of 1–3 months. Low-to-intermediate ischaemic risk and low bleeding risk patients were included and early monotherapy with clopidogrel/ticagrelor was used. All bleeding events were reduced, with a favourable trend towards less ischaemic events including MI. Importantly, more than 50% had ACS as an inclusion criterion. In particular, the Ticagrelor With Aspirin or Alone in High-Risk Patients After Coronary Intervention (TWILIGHT) trial examined the effect of ticagrelor alone vs. ticagrelor plus aspirin with regard to clinically relevant bleeding among patients at high risk for bleeding or ischaemic events who had undergone PCI, according to the inclusion criteria. However, these patients
were not at HBR according to current HBR criteria and event rates at follow-up. Based on this, these patients were more a low bleeding and ischaemic risk cohort even though more than two thirds had an ACS. After 3 months of treatment with ticagrelor plus aspirin, patients who did not have a major bleeding or ischaemic event continued to take ticagrelor and were randomly assigned to receive aspirin or placebo for 1 year. The primary endpoint of Bleeding Academic Research Consortium (BARC) type 2, 3, or 5 bleeding was significantly reduced by omitting aspirin (4.0 vs. 7.1%; HR 0.56, 95% CI 0.45–0.68, P<0.001), with a significant interaction according to ACS at presentation. The trial was not powered for the composite endpoint of death from any cause, non-fatal MI, or non-fatal stroke. However, in exploratory non-inferiority hypothesis testing, there was no signal of increased ischaemic risk. It should be acknowledged that the actual ischaemic event rate in TWILIGHT was low compared to other trials for deemed high-risk PCI patients. Contrary to this, and based on the results of the DAPT and Prevention of Cardiovascular Events in Patients With Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin-Thrombolysis In Myocardial Infarction 54.

In line with guideline recommendations, CAD patients are stratified into two different risk groups (high vs. moderately increased thrombotic or ischaemic risk). Stratification of patients towards complex vs. non-complex CAD is based on individual clinical judgement with knowledge of patients’ cardiovascular history and/or coronary anatomy. Selection and composition of risk-enhancing factors are based on the combined evidence of clinical trials on extended antithrombotic treatment in CAD patients and on data from related registries.

CAD = coronary artery disease; CKD = chronic kidney disease; eGFR = estimated glomerular filtration rate; MI = myocardial infarction; PAD = peripheral artery disease.
increased the risk for major bleeding complications without a bleeding complication, a prolonged DAPT course >12 months should be considered in those with high thrombotic risk and without an increased risk for major or life-threatening bleeding, and may be considered in patients with moderately elevated thrombotic risk (see Figure 7 and Tables 10 and 11). Of note, the 60 mg bis in die [b.i.d. (twice a day)] dose for ticagrelor was better tolerated than the 90 mg b.i.d dose and this dose is now approved in many (albeit not all) countries for this indication.

Switching between oral P2Y12 receptor inhibitors is common and triggers may include bleeding complications (or concerns for bleeding), non-bleeding side effects (e.g. dyspnoea on ticagrelor, allergic reactions), as well as socio-economic factors. Switching between oral P2Y12 receptor inhibitors may be considered in selected cases, and for a more detailed description on switching antiplatelet drugs, please refer to the International Expert Consensus on Switching Platelet P2Y12 Receptor-Inhibiting Therapies and the 2017 ESC DAPT focused update.

DAPT de-escalation (switch from potent drugs like prasugrel or ticagrelor to clopidogrel) in NSTE-ACS patients may be considered as an alternative treatment regimen. However, it is important to note that there is a potential for increased ischaemic risk with a uniform de-escalation of P2Y12 receptor inhibiting therapy after PCI, particularly if performed early (<30 days) after the index event. Indeed, dedicated large-scale trials on a uniform and unguided DAPT de-escalation are lacking and the available data on uniform de-escalation are conflicting. Based on the results of the Testing Responsiveness to Platelet Inhibition on Chronic Antiplatelet Treatment for Acute Coronary Syndromes (TROPICAL-ACS) and POPULAR Genetics trials, an approach of DAPT de-escalation guided by either platelet function testing (TROPICAL-ACS: NSTE-ACS and STEMI patients) or CYP2C19-directed genotyping (POPULAR Genetics: STEMI patients) may be considered in selected NSTE-ACS patients as an alternative to 12 months of potent platelet inhibition, especially for patients deemed unsuitable for maintained potent platelet inhibition. For further details, please refer to the updated expert consensus statement on platelet function and genetic testing for guiding P2Y12 receptor inhibitor treatment in PCI.

Recently, data on a novel strategy of dual antithrombotic therapy (DAT) consisting of factor-Xa inhibition with a very low dose of rivaroxaban (2.5 mg b.i.d.) plus aspirin has emerged, and such a regimen should be considered as a treatment option for maintenance treatment beyond 12 months post ACS PCI. In a secondary prevention setting, the Cardiovascular Outcomes for People using Anticoagulation Strategies (COMPASS) trial investigated very low-dose rivaroxaban (2.5 mg b.i.d.) in combination with aspirin vs. aspirin alone or rivaroxaban 5 mg b.i.d. alone. Rivaroxaban 2.5 mg b.i.d. plus aspirin 100 mg o.d. reduced the risk of the combined ischaemic endpoint, overall mortality (without reaching the threshold P-value according to the Hochberg procedure), and cardiovascular mortality alone, while this combination increased the risk for major bleeding complications without a bleeding complication, a prolonged DAPT course >12 months unless there are contraindications such as excessive risk of bleeding.

### Recommendations for post-interventional and maintenance treatment in patients with non-ST-segment elevation acute coronary syndrome

<td>In patients with NSTE-ACS treated with coronary stent implantation, DAPT with a P2Y12 receptor inhibitor on top of aspirin is recommended for 12 months or more (see Expert Consensus on Dual Antithrombotic Therapy (DAT) consisting of factor-Xa inhibition with a very low dose of rivaroxaban (2.5 mg b.i.d.) in combination with aspirin vs. aspirin alone or rivaroxaban 5 mg b.i.d. alone.</td>
<td>Ia</td>
<td>A</td>
</tr>
</tbody>
</table>

### Prolonging antithrombotic treatment duration

Adding a second antithrombotic agent to aspirin for extended long-term secondary prevention should be considered in patients with a high risk of ischaemic events and without increased risk of major or life-threatening bleeding (see Tables 9 and 11 for options).

Adding a second antithrombotic agent to aspirin for extended long-term secondary prevention may be considered in patients with moderately increased risk of ischaemic events and without increased risk of major or life-threatening bleeding (see Tables 9 and 11 for options).

In ACS patients with no prior stroke/transient ischaemic attack who are at high ischaemic risk and low bleeding risk and are receiving aspirin and clopidogrel, low-dose rivaroxaban (2.5 mg b.i.d. for approximately 1 year) may be considered after discontinuation of parenteral anticoagulation.

### Shortening antithrombotic treatment duration

After stent implantation with high risk of bleeding (e.g. PRECISE-DAPT ≥25 or ARC-HBR criteria met), discontinuation of P2Y12 receptor inhibitor therapy after 3 months should be considered.

After stent implantation in patients undergoing a strategy of DAPT, stopping aspirin after 3–6 months should be considered, depending on the balance between the ischaemic and bleeding risk.

De-escalation of P2Y12 receptor inhibitor treatment (e.g. with a switch from prasugrel or ticagrelor to clopidogrel) may be considered as an alternative DAPT strategy, especially for ACS patients deemed unsuitable for potent platelet inhibition. De-escalation may be done unguided based on clinical judgment or guided by platelet function testing or CYP2C19 genotyping, depending on patient’s risk profile and availability of respective assays.

ACS = acute coronary syndromes; ARC-HBR = Academic Research Consortium – High Blending Risk; b.i.d. = bis in die (twice a day); DAPT = dual antiplatelet therapy; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsequent Dual Antiplatelet Therapy.

*Class of recommendation.

*Level of evidence.
significant increase in the risk of fatal, intracranial, or critical organ bleeding events. Greater absolute risk reductions were seen in high-risk patients, including those with diabetes or polyvascular disease [CAD plus peripheral artery disease (PAD)]. Thus, rivaroxaban (2.5 mg b.i.d.) should be considered, in addition to aspirin 75 - 100 mg/d in patients at high thrombotic risk and without an increased risk for major or life-threatening bleeding, and may be considered in patients with moderately elevated thrombotic risk (see Figure 7 and Tables 10 and 11 for selection criteria and for ischaemic and bleeding risk definitions).

Rivaroxaban has also been studied in the Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Standard Therapy in Subjects with Acute Coronary Syndrome 2—Thrombolysis In Myocardial Infarction 51 (ATLAS ACS 2—TIMI 51) trial on a background of clopidogrel treatment. The study showed a reduction of ischaemic events and cardiovascular mortality along with a higher risk for bleeding. However, data are lacking on a background of ticagrelor or prasugrel treatment and it is therefore difficult to extrapolate trial results to contemporary practice including the use of potent P2Y12 receptor inhibitors.

5.3 Managing oral antiplatelet agents in patients requiring long-term oral anticoagulants

5.3.1 Patients with atrial fibrillation without mechanical prosthetic heart valves or moderate-to-severe mitral stenosis undergoing percutaneous coronary intervention or managed medically (Supplementary Data)

In 6 – 8% of patients undergoing PCI, long-term OAC is indicated and should also be continued during the procedure because its interruption and bridging with parenteral anticoagulants may lead to increased thromboembolic episodes and bleeds. In patients undergoing PCI, it is unknown whether it is safe to bridge non-vitamin K antagonist (VKA) OACs (NOACs) with parenteral anticoagulants or continue NOACs without additional parenteral anticoagulation, while no parenteral anticoagulation is needed if the international normalized ratio (INR) is >2.5 in VKA-treated patients. Strategies to minimize PCI-related complications in patients on OACs are listed in Table 12.

In NSTE-ACS patients, evidence on the management of patients undergoing PCI requiring long-term OAC is derived from subgroups of RCTs (see Table 13 and Supplementary Data section 5.3.1.).

Overall, in patients with AF without mechanical prosthetic valves or moderate-to-severe mitral stenosis, the evidence supports the use of NOACs over VKA in terms of safety (i.e. lower bleeding risk). DAT with a NOAC at the recommended dose for stroke prevention and single antiplatelet therapy (SAPT) (preferably clopidogrel, chosen in more than 90% of cases in available trials) is recommended as the default strategy up to 12 months after a short period (up to 1 week) of triple antithrombotic therapy (TAT) (with NOAC and DAPT) (Figure 8). Although none of the available RCTs were designed to detect subtle differences in ischaemic events, the numerically higher risk of stent thrombosis or MIs observed in some trials might have been offset by the higher risk of bleeding, resulting in a neutral effect on major adverse cardiovascular events (MACE) or overall death. At variance with the default strategy, in patients with HBR, DAT should be shortened to 6 months by withdrawing the ongoing antiplatelet therapy; while in patients with high coronary ischaemic risk, TAT should be prolonged up to 1 month, followed by DAT for up to 12 months. There is currently limited evidence to support the use of OACs with ticagrelor or prasugrel as dual therapy after PCI as an alternative to TAT. Following coronary stenting, DAPT with aspirin and ticagrelor or prasugrel, without OAC, may be considered as an alternative to TAT in patients with high ischaemic risk NSTE-ACS and AF and one non-sex stroke risk factor within the first 4 weeks. Regarding the need to continue with any antiplatelet agent beyond 12 months, the AFIRE trial randomized 2236 AF patients treated with PCI or CABG more than 1 year earlier or with documented CAD to receive either monotherapy with rivaroxaban or combination therapy with rivaroxaban plus a single antiplatelet agent. Rivaroxaban monotherapy (15 mg o.d. or 10 mg o.d. with creatinine clearance (CrCl) 15 – 49 mL/min) was non-inferior to combination therapy for the primary efficacy composite endpoint of stroke, systemic embolism, MI, unstable angina requiring revascularization, or overall death (HR 0.72, 95% CI 0.55 – 0.95).
Table 12  Suggested strategies to reduce bleeding risk related to percutaneous coronary intervention

- Anticoagulant doses adjusted to body weight and renal function, especially in women and older patients
- Radial artery approach as default vascular access
- Proton pump inhibitors in patients on DAPT at higher-than-average risk of gastrointestinal bleeds (i.e. history of gastrointestinal ulcer/haemorrhage, anti-coagulant therapy, chronic non-steroidal anti-inflammatory drugs/corticosteroid use, or two or more of:
  a. Age ≥ 65 years
  b. Dyspepsia
  c. Gastro-oesophageal reflux disease
  d. *Helicobacter pylori* infection
  e. Chronic alcohol use
- In patients on OAC:
  a. PCI performed without interruption of VKAs or NOACs
  b. In patients on VKAs, do not administer UFH if INR > 2.5
  c. In patients on NOACs, regardless of the timing of the last administration of NOACs, add low-dose parenteral anticoagulation (e.g. enoxaparin 0.5 mg/kg i.v. or UFH 60 IU/kg)
- Aspirin is indicated but avoid pre-treatment with P2Y12 receptor inhibitors
- GP IIb/IIIa inhibitors only for bailout or periprocedural complications
- Radial artery approach as default vascular access
- Proton pump inhibitors in patients on DAPT at higher-than-average risk of gastrointestinal bleeds (i.e. history of gastrointestinal ulcer/haemorrhage, anti-coagulant therapy, chronic non-steroidal anti-inflammatory drugs/corticosteroid use, or two or more of:
  a. Age ≥ 65 years
  b. Dyspepsia
  c. Gastro-oesophageal reflux disease
  d. *Helicobacter pylori* infection
  e. Chronic alcohol use

DAPT = dual antiplatelet therapy; GP = glycoprotein; INR = international normalized ratio; i.v. = intravenous; NOAC = non-vitamin K antagonist oral anticoagulant; OAC = oral anticoagulation/anticoagulant; PCI = percutaneous coronary intervention; UFH = unfractionated heparin; VKA = vitamin K antagonist.

A = aspirin; AF = atrial fibrillation; AUGUSTUS = Antithrombotic Therapy after Acute Coronary Syndrome or PCI in Atrial Fibrillation; b.i.d. = bis in die (twice a day); C = clopidogrel; CI = confidence interval; DAT = dual antithrombotic therapy; ENTRUST-AF PCI = Edoxaban N T Treatment vs Us DAT in pATients with AF undergoing PCI; HR = hazard ratio; ISAR-TRIPLE = Triple Therapy in Patients on Oral Anticoagulation After Drug Eluting Stent Implantation; MI = myocardial infarction; OAC = oral anticoagulation/anticoagulant; P = prasugrel; PIONEER AF-PCI = Open-Label, Randomized, Controlled, Multicenter Study Exploring Two Treatment Strategies of Rivaroxaban and a Dose-Adjusted Oral Vitamin K Antagonist Treatment Strategy in Subjects with Atrial Fibrillation who Undergo Percutaneous Coronary Intervention; RCT = randomized controlled trial; RE-DUAL PCI = Randomized Evaluation of Dual Antithrombotic Therapy with Dabigatran versus Triple Therapy with Warfarin in Patients with Nonvalvular Atrial Fibrillation Undergoing Percutaneous Coronary Intervention; T = ticagrelor; TAT = triple antithrombotic therapy; TIMI = Thrombolysis In Myocardial Infarction; VKA = vitamin K antagonist; WOEST = What is the Optimal antiplatelet and anticoagulant therapy in patients with oral anticoagulation and coronary StenTing.
Rivaroxaban monotherapy was superior for the primary safety end-point of major bleeding (HR 0.59, 95% CI 0.39–0.89).

In NSTE-ACS patients managed medically, available data support DAT over TAT, with a single antiplatelet agent (most commonly clopidogrel) for at least 6 months. In a registry, bleeding risk was increased on TAT compared to VKA plus a single antiplatelet agent at 90 days, but not at 1 year, without differences in ischaemic events. In the randomized Antithrombotic Therapy after Acute Coronary Syndrome or PCI in Atrial Fibrillation (AUGUSTUS) trial, approximately 23% of enrolled patients presented with medically managed ACS. In these patients, apixaban significantly reduced bleeding events vs. VKA (HR 0.44, 95% CI 0.28–0.68) and death or hospitalization (HR 0.71, 95% CI 0.54–0.92), while no significant differences were observed in death or ischaemic events (HR 0.71, 95% CI 0.46–1.09). Aspirin vs. placebo presented a strong trend towards higher bleeding events (HR 1.49, 95% CI 0.98–2.26), but no significant differences in death or hospitalization (HR 1.16, 95% CI 0.90–1.51) or ischaemic events (HR 1.01, 95% CI 0.66–1.55).

5.3.2 Patients requiring vitamin K antagonists or undergoing coronary artery bypass surgery

In patients where VKA is mandated (e.g. patients with mechanical prosthetic valves), DAT with VKA and SAPT (preferably clopidogrel) is indicated after a short in-hospital period of TAT (with aspirin and clopidogrel). In addition, warfarin plus clopidogrel resulted in a non-significant reduction in major bleeds compared with TAT, with a non-significant reduction in MI or cardiovascular death. In the randomized Antithrombotic Therapy after Acute Coronary Syndrome or PCI in Atrial Fibrillation (AUGUSTUS) trial, approximately 23% of enrolled patients presented with medically managed ACS. In these patients, apixaban significantly reduced bleeding events vs. VKA (HR 0.44, 95% CI 0.28–0.68) and death or hospitalization (HR 0.71, 95% CI 0.54–0.92), while no significant differences were observed in death or ischaemic events (HR 0.71, 95% CI 0.46–1.09). Aspirin vs. placebo presented a strong trend towards higher bleeding events (HR 1.49, 95% CI 0.98–2.26), but no significant differences in death or hospitalization (HR 1.16, 95% CI 0.90–1.51) or ischaemic events (HR 1.01, 95% CI 0.66–1.55).

Figure 8 Algorithm for antithrombotic therapy in non-ST-segment elevation acute coronary syndrome patients with atrial fibrillation undergoing percutaneous coronary intervention or medical management. Green (class I) and yellow (class IIa) colours denote the classes of recommendation. OAC: preference for a NOAC over VKA for the default strategy and in all other scenarios if no contraindications. For both TAT and DAT regimens, the recommended doses for the NOACs are as follows:

1) Apixaban 5 mg b.i.d.241
2) Dabigatran 110 mg or 150 mg b.i.d.238
3) Edoxaban 60 mg/d
4) Rivaroxaban 15 mg or 20 mg/d240

NOAC dose reductions are recommended in patients with renal failure and may be considered in patients with ARC-HBR (see Table 7). SAPT: preference for a P2Y12 receptor inhibitor over aspirin. Ticagrelor may be considered in patients with high ischaemic risk and low bleeding risk. Treatment >1 month: OAC + DAPT (TAT) may be considered for up to 6 months in selected patients with high ischaemic risk (IIa C). Treatment >12 months: OAC + SAPT may be considered in selected patients with high ischaemic risk. ARC-HBR = see Table 7 and in addition with a PRECISE-DAPT score of ≥25. High thrombotic or ischaemic risk is defined in Table 11. AF = atrial fibrillation; ARC-HBR = Academic Research Consortium — High Bleeding Risk; b.i.d. = bis in die (twice a day); DAPT = dual antiplatelet therapy; DAT = dual antithrombotic therapy; NOAC = non-vitamin K antagonist oral anticoagulant; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; OAC = oral anticoagulation/anticoagulant; PCI = percutaneous coronary intervention; PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; SAPT = single antiplatelet therapy; TAT = triple antithrombotic therapy; VKA = vitamin K antagonist. Listen to the audio guide of this figure online.
Reversal agents might represent an additional option in these patients. In the setting of planned CABG, a 48-h interruption of NOACs is recommended (a longer period might be necessary in patients with impaired renal function). In ACS patients with an established indication for OAC, anticoagulation should be resumed after CABG as soon as the bleeding is controlled, possibly with a combination with SAPT, while TAT should be avoided. For antithrombotic therapy and CABG, see Valgimigli et al.269

Patients undergoing coronary stenting

Anticoagulation

During PCI, additional parenteral anticoagulation is recommended, irrespective of the timing of the last dose of all NOACs and if INR is <2.5 in VKA-treated patients. | I | C |

In patients with an indication for OAC with VKA in combination with aspirin and/or clopidogrel, the dose intensity of VKA should be carefully regulated with a target INR of 2.0–2.5 and a time in the therapeutic range >70%.236,238–241 | IIa | B |

Uninterrupted therapeutic anticoagulation with VKA or NOACs should be considered during the periprocedural phase. | IIa | C |

Antiplatelet treatment

In patients with AF and CHA2DS2-VASc score ≥1 in men and ≥2 in women, after a short period of TAT (up to 1 week from the acute event), DAT is recommended as the default strategy using a NOAC at the recommended dose for stroke prevention and a single oral antiplatelet agent (preferably clopidogrel).238–241,244,245 | I | A |

Periprocedural DAPT administration consisting of aspirin and clopidogrel up to 1 week is recommended.238–241,244,245 | I | A |

Discontinuation of antiplatelet treatment in patients treated with an OAC is recommended after 12 months.236–239,246 | I | B |

In patients treated with a VKA (e.g. mechanical prosthetic valves), clopidogrel alone should be considered in selected patients (HAS-BLED ≥3 or ARC-HBR met and low risk of stent thrombosis) for up to 12 months.236 | IIa | B |

When rivaroxaban is used and concerns about HBR prevail over stent thrombosis or ischaemic stroke, rivaroxaban 15 mg o.d. should be considered in preference to rivaroxaban 20 mg o.d. for the duration of concomitant SAPT or DAPT.240,245 | IIa | B |

In patients at HBR (HAS-BLED ≥3), dabigatran 110 mg b.i.d. should be considered in preference to dabigatran 150 mg b.i.d. for the duration of concomitant SAPT or DAPT to mitigate bleeding risk.238 | IIa | B |

In patients treated with an OAC, aspirin plus clopidogrel for longer than 1 week and up to 1 month should be considered in those with high ischaemic risk or other anatomical/procedural characteristics which outweigh the bleeding risk (Table 17). | IIa | C |

DAT (with an OAC and either ticagrelor or prasugrel) may be considered as an alternative to TAT (with an OAC, aspirin, and clopidogrel) in patients with a moderate or high risk of stent thrombosis, irrespective of the type of stent used. | III | C |

The use of ticagrelor or prasugrel as part of TAT is not recommended.

Medically managed patients

One antiplatelet agent in addition to an OAC should be considered for up to 1 year.241,247 | IIa | C |

In patients with AF, apixaban 5 mg b.i.d. and SAPT (clopidogrel) for at least 6 months may be considered.241,247 | IIb | B |

AF = atrial fibrillation; ARC-HBR = Academic Research Consortium – High Bleeding Risk; b.i.d. = bis in die (twice a day); CABG = coronary artery bypass grafting; CHA2DS2-VASc = Congestive heart failure, Hypertension, Age >75 years (2 points), Diabetes, Stroke (2 points) – Vascular disease, Age 65–74, Sex category (female); DAPT = dual antiplatelet therapy; DAT = dual antithrombotic therapy; HAS-BLED = hypertension, abnormal renal and liver function (1 point each), stroke, bleeding history or predisposition, labile INR, older patients (+65 years), drugs and alcohol (1 point each); HBR = high bleeding risk (see Table 7); ICA = invasive coronary angiography; INR = international normalized ratio; NOAC = non-vitamin K antagonist oral anticoagulant; OAC = oral anticoagulation/anticoagulant; o.d. = once daily; PCI = percutaneous coronary intervention; SAPT = single antiplatelet therapy; TAT = triple antithrombotic therapy; VKA = vitamin K antagonist.

6 Invasive treatments

6.1 Invasive coronary angiography and revascularization

Coronary angiography facilitates clarification as to whether presumed anginal chest pain originates from myocardial ischaemia, as a consequence of a culprit lesion, or not. In the former case, the culprit lesion can subsequently be treated by means of PCI within the same procedure or by CABG, depending on lesion morphology and the patient’s risk profile (see section 6.4). In the latter case, exclusion of a culprit lesion paves the way to subsequent diagnostic investigations ultimately revealing the cause of chest pain and/or myocardial injury (see section 7). However, ICA carries a certain risk for procedure-related complications, which has to be considered in management decisions.

6.1.1 Routine invasive vs. selective invasive approach (Supplementary Data)

Routine invasive strategy means the patient is deemed to undergo ICA. Following a selective invasive strategy, ICA will only be performed after recurrent symptoms, objective evidence of inducible ischaemia on non-invasive testing, or detection of obstructive CAD by CCTA. Multiple RCTs comparing a routine invasive with a selective invasive strategy have been conducted and their results have been pooled in several meta-analyses. The available evidence (Supplementary Table 2) indicates that a routine invasive strategy:

- Does not reduce all-cause mortality risk in the overall population of NSTE-ACS patients.

aClass of recommendation.
bLevel of evidence.
 increases the risk of periprocedural complications such as periprocedural MI and bleeding.

- Reduces the risk of composite ischaemic endpoints, particularly in high-risk patients.

However, the currently available evidence is based on old RCTs that were conducted before critical improvements such as radial access, modern drug-eluting stents (DES), complete functional revascularization for multivessel CAD, modern DAPT, intensified lipid lowering therapy, and contemporary biomarker assays and/or cut-off values for diagnosing spontaneous/periprocedural MI became available.

In summary, the results of RCTs and their meta-analyses highlight the role of risk stratification in the decision process and support a routine invasive strategy in high-risk patients.

6.1.2 Timing of invasive strategy

6.1.2.1 Immediate invasive strategy (<2 h)

Very high-risk NSTE-ACS patients (i.e. with at least one very high-risk criterion according to Figure 9) have generally been excluded from RCTs. Owing to a poor short- and long-term prognosis if left untreated, an immediate invasive strategy (i.e. <2 h from hospital admission, analogous to STEMI management) with the intent to perform revascularization is recommended, irrespective of ECG or biomarker findings. Centres without 24/7 PCI availability must transfer the patient immediately.

6.1.2.2 Early invasive strategy (<24 h)

An early invasive strategy is defined as coronary angiography performed within 24 h of hospital admission. It is recommended in high-risk patients defined according to Figure 9. Multiple RCTs have investigated the optimal timing of ICA and revascularization in NSTE-ACS (Figure 10, Supplementary Table 3). A main limitation for the interpretation of these RCTs is the calculation of time to ICA, which rather than being based on pain onset or on hospital admission time, was based on randomization time. While ICA was virtually always performed within 24 h of randomization in the early invasive strategy groups, the time from randomization to ICA was more heterogeneous in the delayed invasive groups (Figure 10). The two largest RCTs, with more than 1000 patients in each treatment group, are Timing of Intervention in Patients with Acute Coronary Syndromes (TIMACS) and the more contemporary VERDICT trial. There are several important messages that can be derived from these RCTs:

(1) Among unselected NSTE-ACS patients, an early invasive strategy is not superior over a delayed invasive strategy with regard to composite clinical endpoints (Supplementary Table 3).
Several meta-analyses have pooled data of multiple RCTs assessing different timing intervals of ICA (Supplementary Table 4). None of them observed a benefit with an early invasive strategy with respect to the endpoints death, non-fatal MI, or stroke among unselected NSTE-ACS patients.274–278 However, a collaborative meta-analysis comparing an early/immediate invasive to a delayed invasive strategy using a modified individual patient data approach observed a survival benefit in high-risk patients, although tests for interaction were inconclusive.277 Only the VERDICT trial studied the impact of timing on the endpoint hospital admission for heart failure and observed a trend towards less heart failure hospitalization in favor of an early invasive strategy (HR 0.78, 95% CI 0.60–1.01).272 Meta-analyses have consistently reported that an early invasive strategy is associated with a lower risk of recurrent/refractory ischemia and a shorter length of hospital stay.274–276,278 Taken together, an early invasive strategy is recommended in patients with at least one high-risk criterion (Figure 9).

6.1.2.3 Selective invasive strategy

Patients with no recurrence of symptoms and none of the very high- or high-risk criteria listed in the recommendation table regarding timing of invasive strategy are to be considered at low risk of short-term acute ischemic events (Figure 9). These patients should be managed according to the 2019 ESC Guidelines for the diagnosis and management of CCS.231 In this setting, stress echocardiography or stress

Figure 10 Time to coronary angiography in the early/immediate invasive and delayed invasive groups of included trials.271,272,279–287 Bars depict interquartile ranges and median times from randomization to coronary angiography in the early invasive group (red) and delayed invasive group (blue). In addition, description of the main finding of the primary endpoint with an early vs. delayed invasive strategy. Adapted and updated from Jobs et al.277 Based on the individual patient-based meta-analysis patients with elevated biomarkers, GRACE score >140, age >75 years, and diabetes showed a mortality benefit from an early invasive approach.277 ABOARD = Angioplasty to Blunt the Rise of Troponin in Acute Coronary Syndromes Randomized for an Immediate or Delayed Intervention; CK-MB = creatine kinase myocardial band; EARLY = Early or Delayed Revascularization for Intermediate- and High-Risk Non-ST-Segment Elevation Acute Coronary Syndromes; ELISA = Early or Late Intervention in unstable Angina; GRACE = Global Registry of Acute Coronary Events; ISAR-CCD = Intracoronary Stenting and Antithrombotic Regimen – Cooling off strategy; LIPSIA-NSTEMI = Leipzig Immediate versus early and late Percutaneous coronary Coronary Intervention trial in NSTEMI; MACE = major adverse cardiovascular events; MI = myocardial infarction; PCI = percutaneous coronary intervention; RIDDLE-NSTEMI = Randomized Study of Immediate Versus Delayed Invasive Intervention in Patients With Non-ST-Segment Elevation Myocardial Infarction; SISCA = Comparison of Two Treatment Strategies in Patients With an Acute Coronary Syndrome Without ST Elevation; TIMACS = Timing of Intervention in Patients with Acute Coronary Syndromes; VERDICT = Very EaRly vs Deferred Invasive evaluation using Computerized Tomography.

(2) Benefit with an early invasive strategy is strongly associated with the patient’s risk profile. In a pre-specified subgroup analysis, patients with a GRACE risk score >140 benefited from an early invasive strategy while those with a GRACE risk score <140 did not (TIMACS trial: HR 0.65, 95% CI 0.48–0.89 vs. HR 1.12, 95% CI 0.81–1.56, Pinteraction = 0.01;271 VERDICT trial: HR 0.81, 95% CI 0.67–1.00 vs. HR 1.21, 95% CI 0.92–1.60, Pinteraction = 0.02).272

With regard to the GRACE risk score, it must be highlighted that both RCTs calculated the original GRACE risk score for in-hospital death (see Supplementary Figure 3).139 Due to different weighting of variables, scores of other GRACE risk scores (see Supplementary Table 1 for more details) might be considerably different for the same patient, possibly leading to different treatment decisions. Furthermore, in both studies, GRACE risk score calculation was based on elevations of CK-MB or conventional troponin. The value of a GRACE risk score >140 to guide timing of ICA and revascularization in the era of hs-cTn has not been determined.

(3) Benefit with an early invasive strategy is not modified by ST-segment/T-wave changes, despite the fact that ST-segment depression has been consistently identified as a predictor for an adverse outcome (Supplementary Figure 2).

In patients with transient ST-segment elevation and relief of symptoms, an immediate invasive strategy did not reduce CMR-assessed infarct size compared to an early invasive strategy.273

CMR may be preferred over non-invasive anatomical testing. With routine use of hs-cTn and established diagnostic algorithms for NSTE-ACS assessment, ongoing myocardial injury — even low level — can be identified. Therefore, patients previously regarded to be at intermediate risk (e.g. those with a history of revascularization or diabetes mellitus), but ruled out according to a diagnostic algorithm using hs-cTn, should be regarded as low risk and follow a selective invasive strategy.1

6.1.3 Pattern of coronary artery disease in non-ST-segment elevation acute coronary syndrome (Supplementary Data)

6.1.4 How to identify the culprit lesion? (Supplementary Data)

6.1.5 Spontaneous coronary artery dissection

Spontaneous coronary artery dissection (SCAD) is defined as a non-atherosclerotic, non-traumatic, or iatrogenic separation of the coronary arterial tunics secondary to vasa vasmorum haemorrhage or intimal tear, which creates a false lumen, coronary compression, and downstream myocardial ischaemia. SCAD accounts for up to 4% of all ACS, but the incidence is reported to be much higher (22–35% of ACS) in women <60 years of age, in pregnancy-related MI, and in patients with a history of fibromuscular dysplasia, anxiety, depression, or previous neuropsychiatric disorders. Clinical presentations can vary considerably, but elevation of cardiac biomarkers associated with chest discomfort is the most common presentation. There are three angiographic types of SCAD, which range from no obstruction to complete occlusion of the affected coronaries. SCAD Type 1 (contrast dye staining of the arterial wall with multiple radiolucent lumen) and SCAD Type 2 (long diffuse and smooth narrowing) with non-obstructive coronary arteries (stenosis <50%) are described as possible causes of MI with non-obstructive coronary arteries (MINOCA) (see section 7), while SCAD Type 2 with severe coronary obstruction (>50%) and SCAD Type 3 (focal or tubular stenosis that mimics atherosclerosis) should be considered separately. As SCAD may be missed or not be detectable on CCTA, a negative CCTA should not exclude a diagnosis of SCAD. Intra coronary imaging [optical coherence tomography (OCT) and intravascular ultrasound (IVUS)] might be the most accurate options in unclear situations to prove the presence of intramural haematoma or double lumen. This may be fundamental to making a proper diagnosis. The optimal management of SCAD is still unclear, since no RCTs have compared medical therapy to revascularization strategies. According to available data, with the exception of very high-risk profile patients, a conservative approach should be the preferred strategy.

The decision to treat either with a conservative medical approach or to perform PCI or CABG surgery must be individualized and based on both clinical and angiographic factors. A possible treatment algorithm is shown in Figure 11. Optimal medical treatment for patients with SCAD is still undetermined, but because hypertension is an independent predictor of recurrent SCAD, an aggressive anti-hypertensive therapy should be considered to ensure optimal blood pressure control. Beta-blockers, which have been reported to be significantly associated with a reduced risk of
recurrent events, should be the preferred antihypertensive class in this subset of patients. There is controversy regarding the benefit of antithrombotic therapy among these patients, however, among PCI-treated patients, the DAPT algorithms stated in section 5 should be used. Among SCAD patients treated medically and having persistent or recurrent symptoms, even in the absence of recurrent MI or ischaemia, CCTA might be considered for follow-up.

6.1.6 Fractional flow reserve, instantaneous wave-free ratio, and other resting indices (Supplementary Data)

6.1.6.1 Fractional flow reserve

Fractional flow reserve (FFR) is the current standard for the functional assessment of lesion severity in patients with intermediate-grade stenosis (40–90%) without evidence of ischaemia in non-invasive testing, or in those with multivessel disease. Due to microvascular obstruction, the haemodynamic relevance of the culprit lesion in NSTE-ACS may be underestimated. However, it appears reliable for non-culprit lesion estimation when compared to patients with stable CAD. 305 

The majority of the evidence relating to the value of FFR in NSTE-ACS is derived from small subgroups of registries and randomized trials (Supplementary Table 5). In the small Fractional flow reserve versus angiography in guiding management to optimize outcomes in non-ST-elevation myocardial infarction (FAMOUS-NSTEMI) randomized trial, significantly more NSTEMI patients were treated medically with FFR vs. an angio-guided PCI strategy (22.7 vs. 13.2%, P=0.022). This strategy of functional revascularization seems to be safe without any impact on clinical outcomes in NSTE-ACS. However, adequately powered dedicated randomized trials are still lacking.

6.1.6.2 Instantaneous wave-free ratio and other resting indices

There has been renewed interest in resting indices derived from resting gradients alone [distal coronary to aortic pressure ratio (Pd/Pa), iFR, coronary flow reserve (CFR), resting full-cycle ratio (RFR), or the index of microcirculatory resistance (IMR)]. Two large-scale randomized trials showed broadly comparable results between FFR-guided and iFR-guided revascularization strategies in patients with intermediate-grade stenosis. In these trials, the proportion of ACS patients was 15–17%, the non-culprit lesions were investigated, and follow-up was limited to a 1-year duration. For resting indices other than iFR, randomized clinical outcome data are not available.

6.1.7 Intracoronary imaging

Both intracoronary imaging methods, IVUS and OCT, allow real-time tomographic assessment of vessel size, lumen area, plaque composition and volume, as well as stent coverage and expansion. IVUS-guided PCI has been reported to reduce target vessel failure 12 months after PCI compared to angiographically PCI in the Intravascular Ultrasound Guided Drug Eluting Stents Implantation in “All-Comers” Coronary Lesions (ULTIMATE) randomized trial: 2.9 vs. 5.4%, respectively (HR 0.53, 95% CI 0.31–0.90, P=0.019).

Clinically driven target lesion revascularization or definite stent thrombosis was lower with the IVUS-guided strategy [1.2 vs. 2.6%, relative risk (RR) 0.46, 95% CI 0.21–1.03, P=0.05]. However, only 12% of the enrolled patients presented with STEMI or NSTE-ACS, limiting its validity in NSTE-ACS settings. OCT-guided PCI is safe and results in a similar minimum stent area to that of IVUS-guided PCI. In addition, OCT-guided PCI has been shown to lead to higher post-PCI FFR compared to angio-guided PCI among NSTE-ACS patients. Adequately powered trials for clinical endpoints, however, are lacking. Additionally, in patients with MINOCA (see section 7), OCT is a diagnostic tool for evaluating SCAD, erosions, and plaque ruptures.

6.2 Conservative treatment

The established benefit associated with coronary revascularization in NSTE-ACS patients has led to a significant reduction of medical management alone, from 60% two decades ago down to 10–30% in the contemporary era of PCI. Persistent instability of the index of microcirculatory resistance (IMR) is associated with worse clinical outcome compared to patients with stable CAD. Persistent instability of non-haemodynamically significant stenoses or presence of more than one unstable lesion may account for the higher risk.

Medical management should be chosen after careful risk assessment, keeping in mind that ICA using the radial approach is a low-risk procedure, that impaired LV function increases mortality risk, and that coronary anatomy and presence of diabetes may refine the risk stratification and the choice of pharmacological therapy (see Figures 5–7). Advanced age or female sex alone, in the absence of severe comorbidities or frailty, should not be considered as a sufficient reason not to perform PCI and, likewise, ICA should not be denied for logistical reasons.

6.2.1 Patients who are not candidates for invasive coronary angiography

This group represents a small subgroup, where data indicating a hypothetical advantage of an invasive strategy are scarce. Depending on country and world region specific differences, advanced age, female sex, chronic kidney disease (CKD), diabetes mellitus, prior heart failure/revascularization, history of cancer, and frailty are the major reported reasons accounting for withholding diagnostic ICA. These features largely overlap with the predictors of bleeding and ischaemic adverse events and explain the poor prognosis of this population, with in-hospital mortality of 6–9% that rises up to 20 and 50% at 6 months and 3 years, respectively. Medical management should be chosen after careful risk assessment, keeping in mind that ICA using the radial approach is a low-risk procedure, that impaired LV function increases mortality risk, and that coronary anatomy and presence of diabetes may refine the risk stratification and the choice of pharmacological therapy (see Figures 5–7). Advanced age or female sex alone, in the absence of severe comorbidities or frailty, should not be considered as a sufficient reason not to perform PCI and, likewise, ICA should not be denied for logistical reasons.

6.2.2 Patients with coronary artery disease not amenable to revascularization

Patients diagnosed with severe CAD who are not amenable to any type of revascularization are at very high risk of recurrent ischaemic events. Frequently, these patients are women, old and/or suffering from severe CKD, with multivessel CAD, and a history of MI or prior revascularization. The decision not to perform PCI is an independent predictor of increased cardiovascular mortality, both in-hospital and long-term. Accordingly, the decision not to perform revascularization should be made in very selected patients only, where there is consensus that risk outweighs the benefit for clinical or anatomical reasons. These patients should undergo an aggressive secondary...
prevention treatment with potent antiplatelet therapy (see Figures 5—8) and anti-anginal agents, taking their comorbidities into account.325,326

6.3 Technical aspects

6.3.1 Technical aspects and challenges

The principal technical aspects of PCI in NSTE-ACS patients do not differ from the invasive assessment and revascularization strategies for other manifestations of CAD. In patients presenting with NSTE-ACS who are deemed eligible for PCI in one or more vessels, implantation of new-generation DES is the standard of care.159,327,328 While routine thrombectomy has not been proven beneficial in this setting,299,330 The combination and duration of antithrombotic treatment are explained in section 5.

6.3.2 Vascular access

A timely performance of PCI and the use of potent antithrombotic drugs have reduced ischaemic risk in patients with NSTE-ACS. However, this strategy is also invariably associated with an increased bleeding risk, which affects prognosis at least as much as ischaemic complications and is associated with impaired survival.331—333 Among patients undergoing PCI, access-related bleeding accounts for 30—70% of total bleeding events.334 There is accumulative evidence showing that reducing access-site bleeding events with the use of radial access translates into significant clinical benefits. Two large randomized trials, the Radial Vs femorAL access for coronary intervention (RIVAL) trial (n=7021 ACS patients) and the MATRIX trial (n=8404 ACS patients)335,336 have demonstrated significantly lower rates of access site-related bleeding, surgical access site repair, and blood transfusion with radial compared to femoral access. A pairwise meta-analysis comparing radial vs. femoral access in the whole spectrum of patients with CAD, including 30-day follow-up of the MATRIX trial, showed a significant reduction in major bleeds; death, MI, or stroke; and all-cause mortality favouring radial vs. femoral access.337 Although this effect was diluted at 1-year follow-up, net clinical adverse events remained lower with a radial vs. femoral access site.336 Therefore, radial access is recommended as the preferred approach in NSTE-ACS patients undergoing invasive assessment with or without PCI. However, dependent on their haemodynamic situation during index PCI and procedural technical aspects, femoral access might be selectively chosen instead of radial access.

6.3.3 Revascularization strategies

Based on observational studies of patients with NSTE-ACS, the benefit of early intervention — when compared to a conservative approach — may mandate a complete revascularization strategy, irrespective of the possibility to identify and/or treat the culprit lesion.288,277,338—340 Recently, data from the British Cardiac Intervention Society PCI database showed significantly lower cumulative mortality rates with single-stage complete revascularization compared to culprit-lesion-only PCI (22.5 vs. 25.9%, P=0.0005) at a median follow-up of 4.1 years (interquartile range 2.2—5.8) among 21 857 NSTE-ACS patients with multivessel CAD undergoing PCI. This long-term benefit was observed despite an initial increase in inhospital mortality with single-stage complete revascularization (2.3 vs. 1.5%, P=0.002).341 Whether this initial increased risk with single-stage complete revascularization can be reduced by staged complete revascularization needs to be further evaluated.

In contrast to the STEMI setting,342—344 there is only one dedicated randomized trial examining the role of single vs. staged multivessel PCI in NSTE-ACS patients [Impact of Different Treatment in Multivessel Non ST Elevation Myocardial Infarction Patients: One Stage Versus Multistaged Percutaneous Coronary Intervention (SMILE) trial].345 The complete single-stage coronary revascularization resulted in less major adverse cardiovascular and cerebrovascular events (defined as cardiac death, death, reinfarction, rehospitalization for unstable angina, repeat coronary revascularization, and stroke at 1 year) compared to complete coronary revascularization in multistage PCI during the index hospitalization (HR 0.55, 95% CI 0.36—0.83, P=0.004).345 This benefit was largely determined by a significant reduction in repeat revascularization with single-stage multivessel PCI (HR 0.52, 95% CI 0.31—0.88, P=0.01).345 However, since pursuing completeness of revascularization for some patients with complex coronary anatomy may increase the risk of PCI or require CABG, it is reasonable, in the absence of robust clinical data, to tailor the need for, and timing of, complete revascularization to functional relevance of all stenoses, age, general patient condition and comorbidities, and LV function. Furthermore, selection of the revascularization modality may rely on patient preference. For NSTE-ACS patients presenting with CS, randomized evidence does not support routine immediate multivessel PCI (see details in section 8.1).346

6.4 Coronary artery bypass grafting

Approximately 5—10% of NSTE-ACS patients require CABG347 and these represent a challenging subgroup given their high-risk characteristics compared with patients undergoing elective CABG. In the absence of randomized data, optimal timing for non-emergency CABG in NSTE-ACS patients should be determined individually.348 The risk of ischaemic events, possibly related to suboptimal antplatelet therapy while awaiting surgery, is less than 0.1%, while perioperative bleeding complications associated with platelet inhibitors is higher than 10%.349 In patients with ongoing ischaemia or haemodynamic instability and with an indication for CABG, emergency surgery should be performed and not postponed as a consequence of antplatelet treatment exposure.

If CABG is to be performed, every effort should be made to minimize aortic manipulation, work off-pump if there is a calcified aorta or the patient is high risk, achieve complete revascularization, and use graft flow measurement.

6.5 Percutaneous coronary intervention vs. coronary artery bypass surgery

There is no randomized comparison of PCI vs. CABG surgery in the specific setting of NSTE-ACS. In the individual patient data analysis from the Randomized Comparison of Coronary Artery Bypass Surgery and Everolimus-Eluting Stent Implantation in the Treatment of Patients with Multivessel Coronary Artery (BEST), Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus-Eluting Stent in Patients with Left Main Coronary Artery Disease (PRECOMBAT), and Synergy between PCI with Taxus and cardiac surgery (SYNTAX) trials, which compared PCI with CABG, of the 3280 patients with multivessel CAD or left main
6.6 Specific situations

6.6.1 Management of patients with ongoing myocardial ischaemia

These patients are characterized by an overwhelming risk of developing STEMI, onset of life-threatening arrhythmias, acute heart failure, and CS. They should undergo coronary angiography within 2 h of hospital admission with intent to perform revascularization. Based on published data, this approach reduces in-hospital mortality and mortality at early and mid-term follow-up, as well as reducing the risk of new MI in the pre-catheterization period and the length of hospital stay.

6.6.2 Management of patients with cardiac arrest

The management of patients presenting with resuscitated cardiac arrest and concomitant NSTE-ACS needs to be individualized according to their haemodynamic and neurological status.

In out-of-hospital cardiac arrest and no ST-elevation without CS, an unselected immediate invasive strategy is not superior over a delayed invasive strategy, as recently shown in the randomized Coronary Angiography after Cardiac Arrest (COACT) trial. This trial enrolled 552 patients who had been successfully resuscitated after out-of-hospital cardiac arrest and had no signs of STEMI. No difference in 90-day survival was observed between these two strategies, 64.5% in the immediate vs. 67.2% in the delayed angiography strategy (OR 0.89, 95% CI 0.62–1.27, P=0.51). Therefore, it appears reasonable to delay performance of ICA among NSTE-ACS patients. However, several ongoing trials will further define a possible benefit of an early invasive approach.

In comatose survivors, echocardiography should be performed immediately for further evaluation of differential diagnoses. If aortic dissection or pulmonary embolism is suspected, CT is recommended.

### 7 Myocardial infarction with non-obstructive coronary arteries and alternative diagnoses

Although the occurrence of an AMI without significant CAD was initially reported almost 80 years ago, and outcomes were definitely described 13 years ago, the term MINOCA has only been used recently to describe these patients. Accordingly, MINOCA is initially considered at the time of angiography as a working diagnosis until further assessment excludes other possible causes for troponin elevation. This incorporates a heterogeneous group of underlying causes that may involve both coronary and non-coronary pathological conditions, with the latter including cardiac and extra-cardiac disorders. Compared with patients with obstructive CAD, NSTE-ACS patients diagnosed with MINOCA are more likely to be younger and female, and less likely diabetic, hypertensive, or dyslipidaemic, suggesting a predominant role of non-atherosclerotic-related aetiologies and of unusual or usual risk factors like psychosocial aspects, insulin-resistance, and inflammation. However, all studies assessing prognosis in patients with MINOCA are considerably heterogeneous in terms of inclusion criteria, outcomes measurements, and length of follow-up; some report the prevalence of hard endpoints like mortality or reinfarction, but few report outcomes for both MINOCA and CAD populations. Although associated with better prognosis compared to patients with ACS patients with obstructive CAD, the survival rate of MINOCA patients has a lower survival rate than healthy individuals matched for age and sex. Of importance, this excess of adverse events has been reported at both early and late follow-up.

The term MINOCA has been broadly used in the past and is often misclassified, limiting all aspects of disease description, management, and treatment. Despite having a contemporary position statement from the ESC and the AHA, great variability exists in the manner in which patients with suspected MINOCA are evaluated and treated. The extent of the diagnostic and therapeutic strategies implemented often depends on local non-standardized practices and varies widely.

The ESC position statement on MINOCA proposed the following MINOCA criteria:

1. AMI criteria as defined by the Third universal definition of MI.
2. Non-obstructive coronary arteries as per angiographic guidelines, with no lesions >50% in a major epicardial vessel.
3. No other clinically overt specific cause that can serve an alternative cause for the acute presentation.

Based on this ESC definition, myocarditis and Takotsubo syndrome patients, among other non-ischaemic conditions, were labelled as MINOCA.

However, fundamental to the definition of MINOCA is the diagnosis of MI with elevated cardiac biomarkers, typically cardiac troponin >99th percentile of the upper reference level with a rise or fall in the level on serial assessment. Although elevated troponin levels are indicative of myocyte injury with release of this intracellular protein into the systemic circulation, the process is not disease specific and can result from either ischaemic or non-ischaemic mechanisms.

Therefore, the most recent scientific statement from the AHA provides a formal and updated definition for the broadly labelled term MINOCA incorporating the Fourth Universal Definition of Myocardial Infarction. Table 14 provides the current criteria for the MINOCA definition, which by consensus now excludes myocarditis and Takotsubo syndrome from the final diagnosis of MINOCA. Interestingly, in some patients, Takotsubo syndrome may be triggered by NSTEMI or STEMI. Furthermore, with regard to Takotsubo syndrome, there are no RCTs to support a specific treatment and, therefore, all recommendations so far are based on expert opinions.

It also provides a clinically useful framework and algorithms pertaining to the diagnostic evaluation and management of these...

</tbody>
</table>

AMI = acute myocardial infarction; MINOCA = myocardial infarction with non-obstructive coronary arteries.

Note that additional review of the angiogram may be required to ensure the absence of obstructive disease.

patients, which mainly includes a ‘traffic light’ clinical algorithm (Figure 12).

Based on the initial working diagnosis, proper initial assessment of LV wall motion should be promptly performed in the acute setting using LV angiography, depending on renal function, or echocardiography. Regional wall motion abnormalities may indicate an epicardial cause of MINOCA or other specific causes, which may lead to the exclusion of MINOCA. CMR is one of the key diagnostic tools in this algorithm for the differential diagnosis of Takotsubo syndrome, myocarditis, or true MI. CMR has the ability to identify the underlying cause in as many as 87% of patients with MINOCA. In the sub-endocardium, late gadolinium enhancement may indicate an ischaemic cause, while sub-epicardial localization may indicate cardiomyopathies or myocarditis, and the absence of relevant late gadolinium enhancement with oedema and associated specific wall motion abnormalities is a hallmark of Takotsubo syndrome. In a meta-analysis of five studies involving 556 patients with an initial diagnosis of MINOCA, CMR identified myocarditis as the primary cause in 33% of patients.

Intracoronary acetylcholine or ergonovine testing may be performed when coronary or microvascular spasm is suspected. Intracoronary imaging with IVUS or OCT may also be valuable for the detection of unrecognized causes at coronary angiography, especially when thrombus, plaque rupture or erosion, or SCAD are suspected.

Pulmonary embolism should also be considered as an alternative diagnosis as a possible cause of myocardial injury, and this diagnosis may be excluded with additional D-dimer testing, BNP, and/or CT pulmonary angiography, as appropriate. Furthermore, other conditions with an imbalance between myocardial oxygen supply and demand or elevation of cardiac troponin should be considered as potential causes of myocardial injury, such as hypertensive crisis, tachyarrhythmias, sepsis, severe anaemia, and cardiac contusion, among others.

Patients with an initial diagnosis of MINOCA, and an underlying cause identified during the diagnostic work-up, should be treated and followed up according to the guidelines of the specific diagnosis. For example, MINOCA patients discharged with a final diagnosis of NSTE-ACS or MINOCA of unknown cause should be followed up as ACS patients with obstructive CAD. However, despite optimal work-up, the cause of MINOCA remains undetermined in 8–25% of patients. This condition, identified as ‘myocardial infarction of unknown/unclear causes’, represents a therapeutic dilemma. Treatment should target the most probable causes of MINOCA, with negative provocative tests and CMR, namely vasospastic angina, coronary plaque disruption, and thromboembolism. The benefit of DAPT (aspirin + P2Y12 receptor inhibitor) should be considered based on pathophysiological considerations. However, evidence is scarce. Pharmacological therapy with aspirin, statins, angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs), and calcium channel blockers (in case vasospasm is still suspected) as routine treatment may be suggested. These medications have shown significant long-term beneficial effects in terms of all-cause mortality (statins, beta-blockers), cardiovascular death (statins), AMI (beta-blockers), stroke (statins), and MACE (statins, ACE inhibitor/ARB) at 12 months in a national registry. However, this registry did not apply current MINOCA criteria, therefore, the conclusions drawn must be interpreted with caution.
8 Special populations

8.1 Heart failure and cardiogenic shock
Acute heart failure is a frequent complication of NSTE-ACS and is associated with a two to four-fold higher risk of in-hospital mortality compared with NSTE-ACS without acute heart failure.\(^{398-401}\)

The diagnosis of NSTE-ACS in the context of acute heart failure can be challenging because patients with acute heart failure may present with chest discomfort, myocardial injury with troponin
elevation can occur in the absence of obstructive CAD, and the ECG may not be interpretable (bundle branch block or paced rhythm). Consequently, coronary angiography may be required to establish a diagnosis of NSTE-ACS.

The management of acute heart failure should follow current guideline recommendations. Emergency echocardiography should be performed to gather information about the LVEF, regional wall motion abnormalities, right ventricular function, presence of valvular heart disease, and volume loading. The revascularization strategy should be based on the coronary anatomy, LV function, comorbidities, functional relevance of stenoses, and estimated surgical risk according to a Heart Team consensus, and based upon current recommendations.

CS may occur in up to 4% of patients with NSTE-ACS. Ischaemia-related heart failure, acute severe mitral regurgitation, and mechanical complications are the major precipitating causes. These patients should be transferred, as soon as possible, to a tertiary care centre where ICA can be performed. In hub centres, immediate coronary angiography is indicated and PCI should be performed. Nearly 80% of such patients have multivessel CAD. Based on the Culprit Lesion Only PCI versus Multivessel PCI in Cardiogenic Shock (CULPRIT-SHOCK) trial, non-culprit lesions should not be routinely treated immediately, and the immediate PCI strategy should be limited to the culprit lesion only. In CULPRIT-SHOCK, culprit-lesion-only PCI led to a significant reduction in all-cause death or renal-replacement therapy at 30-day follow-up, favouring culprit-lesion-only PCI with possible staged revascularization [RR 0.83, (95% CI 0.71–0.96)]. The risk of all-cause death in the culprit-lesion-only PCI strategy was significantly lower compared to immediate multivessel PCI at 30-day follow-up (RR 0.84, 95% CI 0.72–0.98, P = 0.03). Results for the composite endpoint were maintained at 1-year follow-up, whereas the mortality difference was mainly confined to the first 30 days.

In patients with a coronary anatomy not suitable for PCI, emergency CABG is indicated. Percutaneous mechanical circulatory support devices and/or venoarterial extracorporeal membrane oxygenation may be considered in selected patients, depending on age, comorbidities, neurological function, and severity of CS. Several RCTs are ongoing (Supplementary Table 6). Currently, no survival benefit has been demonstrated for these devices compared with intra-aortic balloon pump (IABP) use. Moreover, in a large retrospective registry of 48306 haemodynamically unstable patients (44% NSTEMI) undergoing PCI, higher mortality and bleeding rates were observed with Impella support compared to IABP. Similar results were observed in another registry confined to CS patients where Impella support was also associated with more complications and higher mortality, even after propensity matching.

As shown in the Intraaortic Balloon Pump in cardiogenic shock (IABP-SHOCK) II trial, IABP does not reduce 30-day, 1-year, or 6-year mortality. Therefore, IABP is not recommended on a routine basis, while its use in situations of ACS-related mechanical complications should be considered.

For NSTE-ACS and stabilized heart failure, evidence-based pharmacotherapies including beta-blockers, ACE inhibitors or ARBs, and mineralocorticoid receptor antagonists (MRAs) should be offered in keeping with current guidelines.

### 8.2 Diabetes mellitus

Patients with diabetes more frequently present with non-typical symptoms than patients without diabetes. They more frequently have multifocal CAD, less frequently receive guideline-indicated care, and have worse clinical outcomes. Nonetheless, the selection of antithrombotics and an invasive strategy should not differ from those without diabetes. Compared with clopidogrel, more potent platelet inhibitors have higher absolute risk reductions in patients with diabetes.

On admission to hospital, it is recommended that all patients with NSTE-ACS have their glycaemic status evaluated, regardless of a history of diabetes, and for it to be monitored frequently in patients with diabetes or hyperglycaemia. Given that, during the acute phase
of NSTEMI, there may be hyperglycaemia, there is the potential for a false positive diagnosis of diabetes. Therefore, the diagnosis of diabetes should be confirmed subsequent to the hospital stay. In critically ill patients, there is a risk of hypoglycaemia-related events when using intensive insulin therapy.\(^{422}\) It is not unreasonable to manage hyperglycaemia in patients with NSTE-ACS by keeping their blood glucose concentration <11.0 mmol/L or <200 mg/dL while avoiding hypoglycaemia, but intensive insulin therapy should not routinely be offered unless clinically indicated. Intensive lipid modification is indicated for secondary prevention.\(^{423}\) A multifactorial approach to diabetes mellitus management, with treatment targets, should be considered in patients with diabetes mellitus and cardiovascular disease (CVD).

ACS = acute coronary syndrome; CVD = cardiovascular disease; NSTE-ACS = non-ST-segment elevation acute coronary syndrome.

\(^{a}\)Class of recommendation.

\(^{b}\)Level of evidence.

### 8.3 Chronic kidney disease

In all patients with NSTE-ACS, assessment of kidney function by eGFR is recommended for prognostic reasons and to identify patients at risk of contrast-induced nephropathy. Although individuals with CKD have a worse prognosis in the setting of NSTE-ACS than individuals with normal renal function, they less frequently receive evidence-based treatments such as antithrombotic agents and early invasive strategy.\(^{437,438}\)

The diagnosis of NSTE-ACS in patients with CKD may be challenging, as both mild elevations in cardiac troponin and ECG abnormalities (e.g. associated with electrolyte disturbances or hypertensive heart disease) are frequent. Therefore, new ECG changes should be differentiated from pre-existing abnormalities and absolute changes in cardiac troponin (i.e. increase and/or decrease) should be assessed to differentiate MI from conditions associated with chronic cardiac injury.

Hs-cTn assays maintain high diagnostic and prognostic accuracy and, therefore, clinical utility in patients with renal dysfunction.\(^{35,89,439}\) A threshold of <5 ng/L may rule out myocardial injury in this population.\(^{89}\) Moreover, patients with troponin concentrations >99th percentile have a two-fold greater risk of cardiac events at 1 year, irrespective of the diagnosis.\(^{89}\)

Patients with advanced kidney disease are less likely to receive an invasive strategy.\(^{440}\) Whilst the overall 1-year mortality is lower with an invasive strategy, the benefit of such a strategy declines with greater reductions in renal function, and with no impact on mortality among patients with eGFR <15 mL/min/1.73 m\(^2\) and in those receiving dialysis.

When an invasive strategy is selected, measures should be taken to prevent contrast-induced nephropathy, for which adequate hydration is the main approach.\(^{441–446}\) High-dose statins, irrespective of the risk of contrast-induced nephropathy, are indicated for secondary prevention.\(^{442}\) For detailed recommendations for contrast-induced nephropathy prevention, consult the 2018 ESC/EACTS Guidelines on myocardial revascularization, section 10.\(^{205}\)

The choice and dose of antithrombotic drugs should be carefully considered in patients with CKD, as these patients have an increased risk of bleeding. While most anticoagulants need dose adjustment in patients with renal insufficiency, this is not the case for oral antiplatelet agents.\(^{447}\) However, for patients with stage 5 CKD (i.e. eGFR <15 mL/min/1.73 m\(^2\)), there are insufficient safety and efficacy data for the use of P2Y\(_12\) receptor inhibitors.

\(^{b}\)Level of evidence.
8.4 Anaemia
Anaemia is common in patients with NSTE-ACS. Persistent or worsening anaemia in patients with NSTE-ACS is associated with increased mortality, recurrent MI, and major bleeding. However, it is uncertain whether anaemia itself is the determinant for poorer outcome or rather a marker of comorbidity.

Given that the treatment of NSTE-ACS includes antithrombotic therapy (which may exacerbate bleeding), it is important to identify the cause of anaemia and, in particular, occult bleeds in patients presenting with NSTE-ACS. The indication for ICA, access site choice (radial approach favoured), and the need for revascularization should be carefully considered to avoid further blood loss. Equally, the choice of antithrombotic agent requires evaluation of ischaemic and bleeding risks, favouring the use of shorter half-life or reversible agents. In the setting of anaemia related to an unknown/untreatable source, the use of DES should be limited to the new-generation devices with proven safety profiles on short-term DAPT.

8.5.2 Heparin-induced thrombocytopenia (Supplementary Data)

8.6 The older person

The clinical presentation of NSTE-ACS in the older person is more often atypical. Among the atypical presentations, dyspnoea is the leading symptom, while syncope, malaise, and confusion are less frequently encountered. Electrocardiographic ST elevation is less frequently present in older than in younger patients. Hs-cTn assays have an excellent diagnostic performance for diagnosing early MI in the older person. However, the specificity of the test is lower in younger patients, and elevated troponin levels are more commonly encountered. The prevalence of frailty. Frail patients with NSTE-ACS less frequently receive ACS pharmacotherapies and an invasive strategy, have more complex CAD, have longer lengths of hospital stay, and are at higher risk of death. Specifically, they are reported to have a higher rate of a composite of all-cause mortality, MI, stroke, unplanned revascularization, and major bleeding at 1 year. In the absence of robust data to inform healthcare professionals about the management of frail people with NSTE-ACS, it is recommended that the risk of individual treatments is balanced against their risk of harm, whilst being mindful of potential for healthcare professional aversion to treatment due to misperception of risk. Following risk stratification, it would not be unreasonable to offer optimal medical therapy plus an invasive strategy to frail patients at high risk of future cardiovascular events and low risk of complications, and to offer optimal medical therapy alone to those who are deemed at low risk of future events with a high risk of developing procedural complications. A systematic review by de Vries et al. identified a range of outcomes instruments to measure frailty (Supplementary Table 7).

8.7 Frailty
Frailty is a syndrome characterized by reduced biological reserve, leading to a failure of homeostatic mechanisms following stressors events. A combination of an aging population, improved disease survival, treatable conditions, and greater awareness has increased the prevalence of frailty. Frail patients with NSTE-ACS less frequently receive ACS pharmacotherapies and an invasive strategy, have more complex CAD, have longer lengths of hospital stay, and are at higher risk of death. Specifically, they are reported to have a higher rate of a composite of all-cause mortality, MI, stroke, unplanned revascularization, and major bleeding at 1 year. In the absence of robust data to inform healthcare professionals about the management of frail people with NSTE-ACS, it is recommended that the risk of individual treatments is balanced against their risk of harm, whilst being mindful of potential for healthcare professional aversion to treatment due to misperception of risk. Following risk stratification, it would not be unreasonable to offer optimal medical therapy plus an invasive strategy to frail patients at high risk of future cardiovascular events and low risk of complications, and to offer optimal medical therapy alone to those who are deemed at low risk of future events with a high risk of developing procedural complications. A systematic review by de Vries et al. identified a range of outcomes instruments to measure frailty (Supplementary Table 7).

8.8 Sex disparities

Data from registries and studies demonstrate discrepant results with respect to access to healthcare, the use of evidence-based therapy, and clinical outcome between men and women presenting with ACS. Moreover, women are often under-represented in many RCTs.
Although several non-invasive testing techniques exist, which may be more appropriate in the detection of microvascular CAD in women, catheterization remains the reference standard for high-risk NSTE-ACS and guidelines should be followed the same for both sexes. Specifically, women who present with NSTE-ACS should be provided with equal access to care, a prompt diagnosis, and treatments at the same rate and intensity as their male counterparts. It should be noted that women with NSTEMI may receive higher antithrombotic medication dosing than appropriate for their weight or renal function (or both), and this is partly responsible for the higher risk of in-hospital bleeds and access-related complications after PCI in women. For recommendations regarding the management of women who are pregnant and have NSTE-ACS, we refer the reader to the 2018 ESC Guidelines for the management of CVD during pregnancy.

9 Long-term management of non-ST-segment elevation acute coronary syndrome

9.1.9 Influenza vaccination (Supplementary Data)

9.2 Pharmacological management (Supplementary Data)

9.2.1 Anti-ischaemic drugs

Often, patients do not continue to experience chest pain after NSTEMI and revascularization. For anti-ischaemic drug management, please refer to the 2019 ESC CCS Guidelines.

9.2.1.1 Beta-blockers (Supplementary Data)

9.2.2 Antithrombotic treatments

Duration of antiplatelet treatment and/or anticoagulation are discussed in section 5.1.4.

9.2.3 Proton pump inhibitors (Supplementary Data)

9.2.4 Statins and other lipid-lowering agents

Dyslipidaemia should be managed, according to lipid guidelines, with pharmacological and lifestyle intervention. Patients with established CAD are regarded as being at very high risk for cardiovascular events, and statin treatment must be considered, irrespective of low-density lipoprotein cholesterol (LDL-C) levels. The goal of treatment is to lower LDL-C to <1.4 mmol/L (<55 mg/dL) and to reduce it by at least 50% if the baseline LDL-C level is 1.8–3.5 mmol/L (70–135 mg/dL). When this level cannot be achieved, the addition of ezetimibe has been demonstrated to decrease cholesterol and cardiovascular events in post-ACS patients, and in patients with diabetes with no further impact on mortality. In addition to exercise, diet, and weight control, which should be recommended to all patients, dietary supplements including phytosterols may lower LDL-C to a lesser extent, but have not been shown to improve clinical outcomes. They may be considered (Class Ib) as an adjunct to pharmacological therapy in high- and very high-risk patients who fail to achieve LDL-C goals on statins and those who cannot be treated with statins. Trials published since 2015 have demonstrated that proprotein convertase subtilisin kexin 9 (PCSK9) inhibitors

10 Quality measures

Quality indicators (QIs) are sets of measures that enable the quantification of adherence to guideline recommendations and provide a mechanism for measuring opportunities to improve cardiovascular care and outcomes. They improve quality by identifying practices that may lead to high-quality care and illustrate how such care was delivered, and have been increasingly used by health authorities, professional organizations, healthcare payers, as well as the public. Typically, QIs are divided into structural, process, and outcome indicators, depending on the aspect of care being measured.

Although high-quality evidence tends to support process QIs, the inclusion of both outcome and process measures enables a more comprehensive evaluation. Additionally, patient-reported outcome measures (PROMs), which may not be underpinned by a strong class of recommendation within guidelines, can be seen as having a complementary role alongside other QIs.

In 2016, the ESC Association for Acute Cardiovascular Care (ACVC), formerly the Acute Cardiovascular Care Association, developed a suite of QIs for the management of AMI with or without ST-segment elevation. These QIs were externally validated in international clinical registries, and most demonstrated an inverse association with mortality.

For this 2020 Guidelines for the management of ACS in patients presenting without persistent ST-segment elevation, the QIs have been updated so that they align to the current recommendations, but also take into account the wider NSTE-ACS pathway of care. Briefly, the ESC ACVC QIs for AMI comprise seven domains, which include the evaluation of: (1) centre organization, (2) the reperfusion/invasive strategy, (3) in-hospital risk assessment, (4) antithrombotic treatment during hospitalization, (5) secondary prevention discharge treatments, (6) patient satisfaction, and (7) composite QI risk-adjusted 30-day mortality. The composite QIs are combinations of individual indicators into a single number to summarize the multiple dimensions and facilitate comparisons and categorization of the centres and can be used by providers for decision making and benchmarking. In this document, however, only the QIs relevant to the management of NSTE-ACS are described and are displayed in Table 15.

The QIs defined here are intended for quality improvement and performance measurement through meaningful surveillance, as well as for integration within registries that specifically aim to identify areas for improvement in clinical practice. The main and secondary QIs represent major and complementary components of the quality of NSTE-ACS care, respectively, and are not intended for ranking healthcare professionals/providers or payment incentives. Continuous monitoring and update will be required for these QIs based on feedback and ‘downstream’ clinical registries data, as well as according to changes in evidence and guideline recommendations.

Continued
3. In-hospital risk assessment

Main QI (1): the proportion of patients who have an assessment of LVEF before hospital discharge. LVEF should be assessed and the numerical value recorded for all patients admitted with NSTE-ACS.

Numerator: number of NSTE-ACS patients who have their LVEF measured before hospital discharge.

Denominator: number of NSTE-ACS patients.

Corresponding ESC CPG recommendation: echocardiography is recommended to evaluate regional and global LV function and to rule in or rule out differential diagnoses.

4. Anti-thrombotic treatment during hospitalization

Main QI: proportion of patients with ‘adequate P2Y12 receptor inhibition’.

Numerator: number of NSTE-ACS patients prescribed adequate P2Y12 inhibitors at the time of hospital discharge.

Denominator: NSTE-ACS patients alive at the time of hospital discharge with an indication for prasugrel, ticagrelor, or clopidogrel.

Corresponding ESC CPG recommendation: a P2Y12 receptor inhibitor is recommended in addition to aspirin, to be maintained over 12 months unless there are contraindications or an excessive risk of bleeding.

5. Secondary prevention discharge treatments

Main QI: proportion of patients discharged from hospital on high-intensity statins (defined as atorvastatin ≥40 mg or rosuvastatin ≥20 mg) unless contraindicated.

Numerator: number of NSTE-ACS patients who receive high-intensity statin therapy at the time of hospital discharge.

Denominator: number of NSTE-ACS patients alive at the time of hospital discharge and without contraindications, refusal, side effects, allergy, or history of intolerance to high-intensity statin therapy.

Corresponding ESC CPG recommendation: statins are recommended in all NSTE-ACS patients. The aim is to reduce LDL-C by at least 50% from baseline and/or achieve LDL-C <1.4 mmol/L (<55 mg/dL).

Secondary QI (1): proportion of patients with LVEF <40% who are discharged from hospital on ACE inhibitor (or ARB if intolerant to ACE inhibitors).

Numerator: number of NSTE-ACS patients with LVEF <40%, prescribed ACE inhibitor/ARB at the time of hospital discharge.

Denominator: number of NSTE-ACS patients with LVEF<40% and alive at the time of hospital discharge who are eligible for ACE inhibitor/ARB (no severe renal impairment, hyperkalaemia, other contraindication, refusal, side effects, or allergy).

Corresponding ESC CPG recommendation: ACE inhibitors (or ARB in cases of intolerance) are recommended in NSTE-ACS patients with co-existing hypertension, LVEF <40%, diabetes, or CKD, unless contraindicated (e.g. severe renal impairment, hyperkalaemia, etc.).

Secondary QI (2): proportion of patients with LVEF <40% who are discharged from hospital on beta-blockers.

Numerator: number of patients with LVEF <40% prescribed beta-blockers at the time of hospital discharge.

Denominator: patients with LVEF<40% and alive at the time of hospital discharge who are eligible for beta-blockers.

Corresponding ESC CPG recommendation: beta-blockers are recommended in patients with systolic LV dysfunction or heart failure with reduced LVEF (<40%).

6. Patient satisfaction

Main QI: feedback regarding the patient’s experience should be systematically collected in an organized way from all patients. It should include the following points:

- Explanations provided by doctors and nurses (about the coronary disease, the benefit/risk of the discharge treatment, and medical follow-up).
- Discharge information regarding what to do in case of recurrence of symptoms and timing of visit.

Numerator: number of NSTE-ACS patients alive at the time of discharge from hospital with feedback collected.

Denominator: number of NSTE-ACS patients discharged from hospital alive.

Corresponding ESC CPG recommendation (1): no ESC CPG recommendation.

Corresponding ESC CPG recommendation (2): no ESC CPG recommendation.
Secondary QI: systematic assessment of health-related quality of life in all patients using a validated instrument.

**Numerator:** number of NSTE-ACS patients alive at the time of hospital discharge who have their health-related quality of life assessed during hospitalization using a validated instrument.

**Denominator:** number of NSTE-ACS patients discharged from hospital alive.

**Corresponding ESC CPG recommendation:** no ESC CPG recommendation.

### 7. CQI

#### Main CQI (opportunity based): with the following individual QIs (all indicators are weighted equally):
- The centre should participate in a regular registry or programme for quality assessment.
- Rate of NSTEMI patients who receive ICA within 24 h of their diagnosis.
- Proportion of patients who have an assessment of LVEF before hospital discharge.
- Proportion of patients with ‘adequate P2Y₁₂ receptor inhibition’.
- Proportion of patients discharged from hospital on high-intensity statins.
- Proportion of patients with LVEF <40% who are discharged from hospital on an ACE inhibitor/ARB.
- Proportion of patients with LVEF <40% who are discharged from hospital on beta-blockers.
- Feedback regarding the patient’s experience systematically collected in an organized way from all patients.

**Numerator:** all NSTE-ACS patients discharged from hospital alive: sum of points (one point for each individual indicator).

**Denominator:** all NSTE-ACS patients discharged from hospital alive: sum of points (one point for each applicable indicator, according to patient and centre characteristics).

**Corresponding ESC CPG recommendation:** no ESC CPG recommendation.

#### Secondary CQI (all or none): based on three or five components, according to LVEF:

- Calculated on three individual QIs in patients with LVEF >40%:
  1. Rate of NSTEMI patients who receive ICA within 24 h of their diagnosis.
  2. Proportion of patients with ‘adequate P2Y₁₂ receptor inhibition’.
  3. Proportion of patients discharged from hospital on high-intensity statins.
- Calculated on five individual QIs in patients with LVEF <40%:
  1. Rate of NSTEMI patients who receive ICA within 24 h of their diagnosis.
  2. Proportion of patients with ‘adequate P2Y₁₂ receptor inhibition’.
  3. Proportion of patients discharged from hospital on high-intensity statins.
  4. Proportion of patients with LVEF <40% who are discharged from hospital on an ACE inhibitor/ARB.
  5. Proportion of patients with LVEF <40% who are discharged from hospital on beta-blockers.

**Numerator:** all NSTE-ACS patients discharged from hospital alive: sum of points (one point for each individual indicator).

**Denominator:** all NSTE-ACS patients discharged from hospital alive: sum of points (one point for each applicable indicator, according to patient and centre characteristics).

**Corresponding ESC CPG recommendation:** no ESC CPG recommendation.

### 8. Outcome QI

#### Secondary QI: risk adjusted 30-day mortality rate.

**Numerator:** all NSTE-ACS patients who died within 30 days after admission.

**Denominator:** all NSTE-ACS patients at 30-day follow-up.

**Corresponding ESC CPG recommendation:** no ESC CPG recommendation.

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; CAD = coronary artery disease; CCS = chronic coronary syndromes; CKD = chronic kidney disease; CPG = clinical practice guidelines; CQI = composite quality indicator; ESC = European Society of Cardiology; hs-cTn = high-sensitivity cardiac troponin; ICA = invasive coronary angiography; LDL-C = low-density lipoprotein cholesterol; LV = left ventricular; LVEF = left ventricular ejection fraction; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; NSTEMI = non-ST-segment elevation myocardial infarction; QI = quality indicator.

Class of recommendation.

Risk-adjusted 30-day mortality rates (i.e. using a logistic regression model adjusted for the risk score (by a validated risk score assessment), with 30-day mortality as the dependent variable.)
11 Management strategy

Figure 13 describes an overview and management pathway for NSTE-ACS patients.

Figure 13 Central illustration. Management strategy for non-ST-segment elevation acute coronary syndrome patients. BNP = B-type natriuretic peptide; CABG = coronary artery bypass graft(ing); CCU = coronary care unit; DAPT = dual antiplatelet therapy; DES = drug-eluting stent; ECG = electrocardiogram/electrocardiography; GP = glycoprotein; GRACE = Global Registry of Acute Coronary Events; hs-cTn = high-sensitivity cardiac troponin; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; NSTEMI = non-ST-segment elevation myocardial infarction; NT-proBNP = N-terminal pro-B-type natriuretic peptide; PCI = percutaneous coronary intervention; PCSK9 = proprotein convertase subtilisin kexin 9; UFH = unfractionated heparin. Listen to the audio guide of this figure online.
12 Key messages

• **Diagnosis.** Chest discomfort without persistent ST-segment elevation (NSTE-ACS) is the leading symptom initiating the diagnostic and therapeutic cascade. The pathological correlate at the myocardial level is cardiomyocyte necrosis, measured by troponin release, or, less frequently, myocardial ischaemia without cell damage (unstable angina). Individuals with unstable angina have a substantially lower risk of death and derive less benefit from an aggressive pharmacological and invasive approach.

• **Troponin assays.** High-sensitivity troponin assays measurements are recommended over less sensitive ones, as they provide higher diagnostic accuracy at identical low cost. It should be noted that many cardiac pathologies other than MI also result in cardiomyocyte injury and, therefore, cardiac troponin elevations.

• **Other biomarkers.** Other biomarkers may have clinical relevance in specific clinical settings when used in combination with non-hs-cTn T/I. CK-MB shows a more rapid decline after MI and may provide added value for detection of early reinfarction. The routine use of copepitin as an additional biomarker for the early rule-out of MI is recommended in the increasingly uncommon setting where hs-cTn assays are not available.

• **Rapid ‘rule-in’ and ‘rule-out’ algorithms.** Due to the higher sensitivity and diagnostic accuracy for the detection of MI at presentation, the time interval to the second cTn assessment can be shortened with the use of hs-cTn assays. It is recommended to use the 0 h/1 h algorithm (best option, blood draw at 0 h and 1 h) or the 0 h/2 h algorithm (second-best option, blood draw at 0 h and 2 h). Optimal thresholds for rule-out and rule-in were selected to allow for a minimal sensitivity and NPV of 99% and a minimal PPV of 70%. Used in conjunction with clinical and ECG findings, the 0 h/1 h and 0 h/2 h algorithm allows the identification of appropriate candidates for early discharge and outpatient management.

• **Confounders of hs-cTn.** Beyond the presence or absence of MI, four clinical variables affect hs-cTn concentrations. The effect of age (differences in concentration between healthy very young vs. ‘healthy’ very old individuals up to 300%), renal dysfunction (differences in concentration between otherwise healthy patients with very high vs. very low eGFR up to 300%), and chest pain onset (>300%) is substantial, and modest for sex (≈40%).

• **Ischaemic risk assessment.** Initial cTn levels add prognostic information in terms of short- and long-term mortality to clinical and ECG variables. The higher the hs-cTn levels, the greater the risk of death. Serum creatinine and eGFR should also be determined in all patients with NSTE-ACS because they affect prognosis and are key elements of the GRACE risk score, which assessment is superior to (subjective) physician assessment for the occurrence of death or MI. Natriuretic peptides may provide incremental prognostic information and may help in risk stratification.

• **Bleeding risk assessment.** ARC-HBR is a pragmatic approach that includes the most recent trials performed in HBR patients, who were previously excluded from clinical trials of DAPT duration or intensity. The PRECISE-DAPT score may be used to guide and inform decision making on DAPT duration with a modest predictive value for major bleeding. Their value in improving patient outcomes remains unclear.

• **Non-invasive imaging.** Even after the rule-out of MI, elective non-invasive or invasive imaging may be indicated according to clinical assessment. CCTA may be an option in patients with low-to-moderate clinical likelihood of unstable angina as a normal scan excludes CAD. CCTA has a high NPV to exclude ACS (by excluding CAD) and an excellent outcome in patients presenting to the emergency department with low-to-intermediate pre-test probability for ACS and a normal CCTA. In addition, upfront imaging with CCTA reduces the need for ICA in high risk patients. Stress imaging by cardiac magnetic resonance imaging, stress echocardiography, or nuclear imaging may also be an option based on risk assessment.

• **Risk stratification for an invasive approach.** An early routine invasive approach within 24 h of admission is recommended for NSTEMI based on hs-cTn measurements, GRACE risk score >140, and dynamic new, or presumably new, ST-segment changes as it improves major adverse cardiac events and possibly early survival. Immediate invasive angiography is required in unstable patients according to hemodynamic status, arrhythmias, acute heart failure, or persistent chest pain. In all other clinical presentation, a selective invasive approach may be performed according to non-invasive testing or clinical risk assessment.

• **Revascularization strategies.** The principal technical aspects of PCI in NSTE-ACS patients do not differ from the invasive assessment and revascularization strategies for other manifestations of CAD. Radial access is recommended as the preferred approach in NSTE-ACS patients undergoing invasive assessment with or without PCI. Multivessel disease is frequent in NSTE-ACS, timing and completeness of revascularization should be decided according to functional relevance of all stenoses, age, general patient condition, comorbidities, and left ventricular function.

• **Myocardial infarction with non-obstructive coronary arteries.** MINOCA incorporates a heterogeneous group of underlying causes that may involve both coronary and non-coronary pathological conditions, with the latter including cardiac and extra-cardiac disorders. It excludes by consensus myocarditis and Takotsubo syndrome. Cardiac magnetic resonance imaging is one of the key diagnostic tools as it identifies the underlying cause in more than 85% of patients and the subsequent appropriate treatment.

• **Spontaneous coronary artery dissection.** Defined as a non-atherosclerotic, non-traumatic, or iatrogenic separation of the coronary arterial tunics secondary to vasa vasaorum hemorrhage or intimal tear, it accounts for up to 4% of all ACS, but the incidence is reported to be much higher (22 – 35% of ACS) in women <60 years of age. Intracoronary imaging is very useful for the diagnosis and treatment orientation. Medical treatment remains to be established.

• **Pre-treatment with P2Y12 receptor inhibitors.** Routine pre-treatment with a P2Y12 receptor inhibitor in NSTE-ACS patients in whom coronary anatomy is not known and an early invasive management is planned is not recommended given the lack of established benefit. However, it may be considered in selected cases and according to the bleeding risk of the patient.
- **Post-treatment antiplatelet therapy.** DAPT consisting of a potent P2Y$_{12}$ receptor inhibitor in addition to aspirin is generally recommended for 12 months, irrespective of the stent type, unless there are contraindications. New scenarios have been implemented. DAPT duration can be shortened (<12 months), extended (>12 months), or modified by switching DAPT or de-escalation. These decisions depend on individual clinical judgment being driven by the patient’s ischaemic and bleeding risk, the occurrence of adverse events, comorbidities, co-medications, and the availability of the respective drugs.

- **Triple antithrombotic therapy.** In at least 6 – 8% of patients undergoing PCI, long-term oral anticoagulation is indicated and should be continued. NOACs are preferred over VKAs in terms of safety when patients are eligible. DAT with a NOAC at the recommended dose for stroke prevention and SAPT (preferably clopidogrel, chosen in more than 90% of cases in available trials) is recommended as the default strategy up to 12 months after a short period up to 1 week of TAT (with NOAC and DAPT). TAT may be prolonged up to 1 month when the ischaemic risk outweighs the bleeding risk.

### 13 Gaps in evidence for non-ST-segment elevation acute coronary syndrome care and future research

</tr>
<tr>
<td>Mainly due to difficulties in enrolment, older patients have been under-represented in clinical trials of invasive strategies for NSTE-ACS patients.</td>
<td>Multicentre RCTs evaluating the safety and effectiveness of different treatment strategies in sufficient numbers of older NSTE-ACS patients.</td>
</tr>
</tbody>
</table>

Continued
We do not know whether there are additional criteria for not waiting at all in the NSTE-ACS population, apart from those currently listed in the immediate invasive strategy.

It remains unclear whether coronary revascularization of the presumed culprit lesion only or complete revascularization in NSTE-ACS patients should be attempted.

The value of haemodynamic assessment based on FFR of non-culprit lesions to guide complete revascularization in the NSTE-ACS setting remains unclear.

Should PCI or CABG be the preferred option in multivessel coronary disease in NSTE-ACS?

Should complete revascularization be achieved during the index intervention or as a staged approach?

The role and type of percutaneous mechanical circulatory support device in patients presenting with NSTE-ACS and CS remains uncertain.

LONG-TERM MANAGEMENT

The optimal mode of training programmes following NSTE-ACS should be determined.

It has to be determined whether neprilysin inhibitors — in the specific group of patients who have suffered NSTE-ACS with systolic LV dysfunction — improve clinical outcomes and reduce hospitalizations.

What is the value of long-term beta-blocker and long-term ACE inhibitor/ARB in patients with normal LV function and no other indications for these therapies?

What is the optimal long-term antithrombotic therapy in NSTE-ACS patients who have undergone percutaneous coronary revascularization?

The impact of heart valve disease in patients with CAD and NSTE-ACS is unknown and needs to be investigated.

patients presenting with NSTE-ACS and multivessel disease randomized to PCI as indicated with vs. without FFR of non-culprit lesions.

Dedicated trials focused on NSTE-ACS patients with multivessel coronary disease randomized to PCI vs. CABG including invasive and/or non-invasive assessment.

Immediate vs. staged complete revascularization should be evaluated in RCTs in patients with multivessel disease.

Strategies based on percutaneous mechanical circulatory support devices in NSTE-ACS patients presenting with CS should be evaluated compared to standard of care.

 Patients randomized to different modes of rehabilitation programmes after NSTE-ACS.

NSTE-ACS patients with systolic LV dysfunction should be randomized to therapy with a neprilysin inhibitor vs. standard of care.

RCTs comparing the long-term continuation of therapy with beta-blockers and ACE inhibitor/ARB to withdrawal in patients with normal LV function in the absence of other indications following NSTE-ACS.

Dedicated RCTs comparing different combinations of potent antithrombotic agents and examining the benefit-risk balance for ischaemic/bleeding events.

Strategies based on revascularization only vs. revascularization and heart valve disease treatment should be evaluated (non-severe valvular heart disease including aortic stenosis and mitral regurgitation).

ACE = angiotensin-converting enzyme; ACS = acute coronary syndromes; ARB = angiotensin receptor blocker; ARC-HBR = Academic Research Consortium - High Bleeding Risk; CABG = coronary artery bypass grafting; CAD = coronary artery disease; CCTA = coronary computed tomographic angiography; CS = cardiogenic shock; DAPT = dual antiplatelet therapy; FFR = fractional flow reserve; FFR-CT = fractional flow reserve-computed tomography; hs-cTn = high-sensitivity cardiac troponin; ICA = invasive coronary angiography; i.e. = intravenous; LV = left ventricular; LVEF = left ventricular ejection fraction; NSTE-ACS = non-ST elevation acute coronary syndrome; NSTEMI = non-ST-segment elevation myocardial infarction; PCI = percutaneous coronary intervention; PRECISE-DAPT = PREDicting bleeding Complications In patients undergoing Stent implantation and subsequent Dual Anti-Platelet Therapy; RCT = randomized controlled trial.
The ESC 0 h/1 h algorithm with blood sampling at 0 h and 1 h is recommended if an hs-cTn test with a validated 0 h/1 h algorithm is available.30,33,35,36,39,68,69,75,76

Additional testing after 3 h is recommended if the first two cardiac troponin measurements of the 0 h/1 h algorithm are not conclusive and the clinical condition is still suggestive of ACS.85

As an alternative to the ESC 0 h/1 h algorithm, it is recommended to use the ESC 0 h/2 h algorithm with blood sampling at 0 h and 2 h, if an hs-cTn test with a validated 0 h/2 h algorithm is available.33,39,75,78,84

Additional ECG leads (V3R, V4R, V7–V9) are recommended if ongoing ischaemia is suspected when standard leads are inconclusive.

For initial diagnostic purposes, it is not recommended to routinely measure additional biomarkers such as h-FABP or copeptin, in addition to hs-cTn.37,48,51,52,118

**Imaging**

In patients presenting with cardiac arrest or haemodynamic instability of presumed cardiovascular origin, echocardiography is recommended and should be performed by trained physicians immediately following a 12-lead ECG.

In patients with no recurrence of chest pain, normal ECG findings, and normal levels of cardiac troponin (preferably high sensitivity), but still with a suspected ACS, a non-invasive stress test (preferably with imaging) for inducible ischaemia or CCTA is recommended before deciding on an invasive approach.91,92,98,101,105,108

Echocardiography is recommended to evaluate regional and global LV function and to rule in or rule out differential diagnoses.5

CCTA is recommended as an alternative to ICA to exclude ACS when there is a low-to-intermediate likelihood of CAD and when cardiac troponin and/or ECG are normal or inconclusive.105,108,110

**Monitoring**

Continuous rhythm monitoring is recommended until the diagnosis of NSTEMI has been established or ruled out.

It is recommended to admit NSTEMI patients to a monitored unit.

Rhythm monitoring up to 24 h or to PCI (whichever comes first) is recommended in NSTEMI patients at low risk for cardiac arrhythmias.4

Rhythm monitoring for >24 h is recommended in NSTEMI patients at increased risk for cardiac arrhythmias.5

**Recommendations on biomarker measurements for prognostic stratification**

Beyond its diagnostic role, it is recommended to measure hs-cTn serially for the estimation of prognosis.12,13,119,120

The measurement of additional biomarkers, such as mid-regional pro-A-type natriuretic peptide, high-sensitivity C-reactive protein, mid-regional pro-adrenomedullin, GDF-15, copeptin, and h-FABP is not recommended for routine risk or prognosis assessment.50,127,129

**Recommendations for antithrombotic treatment in non-ST-segment elevation acute coronary syndrome patients undergoing percutaneous coronary intervention**

**Antiplatelet treatment**

Aspirin is recommended for all patients without contraindications at an initial oral LD of 150 – 300 mg (or 75 – 250 mg i.v.), and at a MD of 75 – 100 mg o.d. for long-term treatment.179,181

A P2Y12 receptor inhibitor is recommended in addition to aspirin, and maintained over 12 months unless there are contraindications or an excessive risk of bleeding.170,171,182

Options are:

- Prasugrel in P2Y12 receptor inhibitor-naïve patients proceeding to PCI (60 mg LD, 10 mg/d as standard dose, 5 mg/d for patients aged ≥75 years or with a body weight <60 kg).171

- Ticagrelor irrespective of the planned treatment strategy (invasive or conservative) (180 mg LD, 90 mg b.i.d.).170

- Clopidogrel (300 – 600 mg LD, 75 mg daily dose), only when prasugrel or ticagrelor are not available, cannot be tolerated, or are contraindicated.182,183

Treatment with GP IIb/IIIa antagonists in patients in whom coronary anatomy is not known and is not recommended.188,189

It is not recommended to administer routine pre-treatment with a P2Y12 receptor inhibitor in patients in whom coronary anatomy is not known and an early invasive management is planned.174,177,190,191

**Peri-interventional anticoagulant treatment**

Parenteral anticoagulation is recommended for all patients, in addition to antiplatelet treatment, at the time of diagnosis and, especially, during revascularization procedures according to both ischaemic and bleeding risks.192,193

UFH (weight-adjusted i.v. bolus during PCI of 70 – 100 IU/kg, or 50 – 70 IU/kg in combination with a GP IIb/IIIa inhibitor; activated clotting time target range of 250 – 350 s, or 200 – 250 s if a GP IIb/IIIa inhibitor is given) is recommended in patients undergoing PCI.

In cases of medical treatment or logistical constraints for transferring the patient to PCI within the required time frame, fondaparinux is recommended and, in such cases, a single bolus of UFH is recommended at the time of PCI.183
It is recommended to select anticoagulation according to both ischaemic and bleeding risks, and according to the efficacy–safety profile of the chosen agent.

Crossover of UFH and LMWH is not recommended.196

**Recommendations for post-interventional and maintenance treatment in patients with non-ST-segment elevation acute coronary syndrome**

In patients with NSTE-ACS treated with coronary stent implantation, DAPT with a P2Y₁₂ receptor inhibitor on top of aspirin is recommended for 12 months unless there are contraindications such as excessive risk of bleeding.170,171,225

**Recommendations for anti-ischaemic drugs in the acute phase of non-ST-segment elevation acute coronary syndrome**

Sublingual or i.v. nitrates and early initiation of beta-blocker treatment are recommended in patients with ongoing ischaemic symptoms and without contraindications.

It is recommended to continue chronic beta-blocker therapy unless the patient is in overt heart failure.

i.v. nitrates are recommended in patients with uncontrolled hypertension or signs of heart failure.

**Recommendations for combining antiplatelet agents and anticoagulants in non-ST-segment elevation acute coronary syndrome patients requiring chronic oral anticoagulation**

Stroke prevention should be offered to AF patients with >1 non-sex CHA₂DS₂-VASc stroke risk factors (score of >1 in males or >2 in females). For patients with >2 non-sex stroke risk factors, OAC is recommended.255–259

**Patients undergoing coronary stenting**

**Anticoagulation**

During PCI, additional parenteral anticoagulation is recommended, irrespective of the timing of the last dose of all NOACs and if INR is <2.5 in VKA-treated patients.

**Antiplatelet treatment**

In patients with AF and CHA₂DS₂-VASc score ≥1 in men and ≥2 in women, after a short period of TAT (up to 1 week from the acute event), DAT is recommended as the default strategy using a NOAC at the recommended dose for stroke prevention and a single oral antiplatelet agent (preferably clopidogrel).238–241,244,245

Periprocedural DAPT administration consisting of aspirin and clopidogrel up to 1 week is recommended.238–241,244,245

Discontinuation of antiplatelet treatment in patients treated with an OAC is recommended after 12 months.236–239,246

The use of ticagrelor or prasugrel as part of TAT is not recommended.

**Recommendations for combining antiplatelet agents and anticoagulants in non-ST-segment elevation acute coronary syndrome patients requiring chronic oral anticoagulation**

**Timing of invasive strategy**

An immediate invasive strategy (<2 h) is recommended in patients with at least one of the following very high-risk criteria:

- Haemodynamic instability or CS.
- Recurrent or refractory chest pain despite medical treatment.
- Life-threatening arrhythmias.
- Mechanical complications of MI.
- Heart failure clearly related to NSTE-ACS.
- Presence of ST-segment depression >1 mm in ≥6 additional to ST-segment elevation in aVR and/or V1.

An early invasive strategy within 24 h is recommended in patients with any of the following high-risk criteria:

- Diagnosis of NSTEMI suggested by the diagnostic algorithm recommended in section 3.
- Dynamic or presumably new contiguous ST/T-segment changes suggesting ongoing ischaemia.
- Transient ST-segment elevation.271,362
- GRACE risk score >140.271,272,277

A selective invasive strategy after appropriate ischaemia testing or detection of obstructive CAD by CCTA is recommended in patients considered at low risk.267,268,363

**Technical aspects**

Radial access is recommended as the standard approach, unless there are overriding procedural considerations.336,337

DES are recommended over bare-metal stents for any PCI irrespective of:

- Clinical presentation.
- Lesion type.
- Planned non-cardiac surgery.
- Anticipated duration of DAPT.
- Concomitant anticoagulant therapy.354,365,366

Continued
It is recommended to base the revascularization strategy (ad hoc culprit lesion PCI/multivessel PCI/CABG) on the patient’s clinical status and comorbidities, as well as their disease severity [i.e. the distribution and angiographic lesion characteristics (e.g. SYNTAX score)], according to the principles for stable CAD. However, the decision on immediate PCI of the culprit stenosis does not require Heart Team consultation.

</table>
Recommendations for pharmacological long-term management after non-ST-segment elevation acute coronary syndrome (excluding antithrombotic treatments)

**Lipid-lowering drugs**

Statins are recommended in all NSTE-ACS patients. The aim is to reduce LDL-C by ≥50% from baseline and/or to achieve LDL-C <1.4 mmol/L (<55 mg/dL).533,534

- If the LDL-C goal is not achieved after 4–6 weeks with the maximally tolerated statin dose, combination with ezetimibe is recommended.514,535
- If the LDL-C goal is not achieved after 4–6 weeks despite maximally tolerated statin therapy and ezetimibe, the addition of a PCSK9 inhibitor is recommended.520,535

**ACE inhibitors or ARBs**

ACE inhibitors (or ARBs in cases of intolerance to ACE inhibitors) are recommended in patients with heart failure with reduced LVEF (<40%), diabetes, or CKD unless contraindicated (e.g. severe renal impairment, hyperkalaemia, etc.) in order to reduce all-cause and cardiovascular mortality and cardiovascular morbidity.536–538

**Beta-blockers**

Beta-blockers are recommended in patients with systolic LV dysfunction or heart failure with reduced LVEF (<40%).539–541

**MRAs**

MRAs are recommended in patients with heart failure with reduced LVEF (<40%) in order to reduce all-cause and cardiovascular mortality and cardiovascular morbidity.548,549

**Proton pump inhibitors**

Concomitant use of a proton pump inhibitor is recommended in patients receiving aspirin monotherapy, DAPT, DAT, TAT, or OAC monotherapy who are at high risk of gastrointestinal bleeding in order to reduce the risk of gastric bleeds.169
